should be examined for typical bacilli. The isolated bacilli can be identified by the following criteria. *Y. pestis*, the sole *Yersinia* spp. that is nonmotile at 37° C and 22° C (98.6° F and 71.6° F), also is the sole *Yersinia* spp. that is urease negative, but it may be positive in freshly isolated strains. The organism is positive for esculin, β-galactosidase, catalase, and methyl red. Oxidase, indole, and Voges-Proskauer reactions are negative. It ferments glucose, maltose, salicin, xylose, arabinose, dextrin, trehalose, and mannitol. It does not produce acid from lactose, sucrose, rhamnose, melibiose, adonitol, cellobiose, sorbose, or dulcitol. It does not use citrate, and it does not grow in potassium cyanide. *Y. pestis* is negative for lysine, ornithine decarboxylase, and arginine dihydrolase.[44,53]

Positive cultures show pinpoint colonies within 24 to 48 hours after inoculation. Many laboratories use fully automated or semiautomated identification systems (e.g., Vitek) that may not detect *Y. pestis*, often confusing *Y. pestis* and *Y. pseudotuberculosis* or *Yersinia enterocolitica* with plague bacillus. Nonautomated laboratories may require 6 days to identify the organism. Because of lack of standardized susceptibility testing procedures, suspected isolates must be referred to public health or other reference laboratories to comply with the select agent requirements of the Title II Enhanced Controls for Dangerous Biological Agents and Toxins Act.[28]

Several chromosomal-mediated virulence factors are responsible for the virulence of *Y. pestis*, including (1) an antiphagocytic capsular material known as fraction 1, (2) the endogenous purine synthesis that allows the organism to grow within macrophages, and (3) the ability to absorb iron from the medium.[5] Several plasmids have been implicated in the development of other virulence factors.[24,57] A plasmid of 9-kb pairs contains the determinant of secretory protein that kills other bacterial strains. A plasmid of 72-kb pairs, which all pathogenic *Y. pestis* strains contain, confers the requirement for environmental calcium to be present for the organism to grow at 37° C (98.6° F). When grown under this condition, *Y. pestis* produces V and W antigens that are necessary for virulence.[21] An exotoxin and an endotoxin have been found to contribute to the lethal effects of plague.[53,62]

TRANSMISSION

Host

More than 200 mammalian species have been reported to be naturally infected with *Y. pestis*. Epidemics of plague usually are transmitted by the fleas of infected domestic rats, however. This form of spread is more likely to occur in urban, rat-infested, and crowded dwellings and may result in epidemics. In the United States, plague is transmitted sporadically to humans after contact with an enzootic sylvatic focus.[31] Infected wild rodents perpetuate the plague bacillus in a given ecosystem by virtue of their ability to withstand an inoculum of *Y. pestis* many times greater than that necessary to cause disease in humans or domestic animals. After inoculation, wild rodents may become bacteremic and infect fleas that feed on them; these fleas transmit the plague bacillus to another rodent. Hibernating animals are especially resistant to clinical infection. Animals inoculated before going into hibernation may survive through the winter and not die until after they come out of their burrows, reintroducing the bacillus in the new season.[25] Carnivores are relatively resistant to infection but contribute to the spread of the organism by transporting infected fleas from one area to another.[31,61]

The role of domestic animals in bridging the gap between sylvatic plague and human infection has been studied extensively.[29,41,47] Cats and dogs are susceptible to natural and experimental plague.[56] Epizootics in cats have been observed in conjunction with plague epidemics in humans.[47] Experimentally infected cats develop severe systemic illness, with bacteremia and abscess formation at the site of the inoculum. Between 1977 and 1998, 23 cases of feline-associated human plague infection were reported.[22] Five of these cases were fatal; two of the patients had primary pneumonic plague, and one had septicemic plague. Many of these cases were misdiagnosed at presentation, leading to delays in treatment and, in some cases, fatalities. This diagnosis should be considered especially in the western states of Arizona, California, Colorado, and New Mexico. No seasonal variation in the occurrence of cat-associated illness was noted.[20,22]

Ten other cases reported in the literature of feline transmission of plague to humans involved four veterinarians.[18] Dogs also are susceptible, but the disease is milder.[29] Swine are resistant to plague, the only evidence of subclinical infection being the presence of antibodies to the fraction 1 antigen of *Y. pestis*. Domestic animals, by virtue of their intimate contact with wildlife and humans, may be responsible for some cases of human plague. This danger is accentuated by a dearth of symptoms in some animals.[41]

Vector

Plague is transmitted to humans by the bite of an infected flea, the skinning and evisceration of infected animals,[32] or the inhalation of infected droplets from a case of pneumonic plague.[35] Infrequent portals of entry include the conjunctiva[41] and the pharynx.[40,49]

The efficiency of the flea as a vector for human disease depends on the likelihood that the infected flea will feed on a person and that the flea will regurgitate the bacillus into the victim's bloodstream in the process of feeding.[31] Flea species vary in both of these attributes. Wild rodent fleas are reluctant to feed on humans and do it only under duress (e.g., when the natural host dies). Fleas of domestic animals are more likely to bite humans. The Oriental rat flea, *Xenopsylla cheopis*, is the most efficient transmitter of plague because of its willingness to bite people and its propensity for regurgitating large numbers of bacilli in the process.[31] When the Oriental rat flea ingests infected blood, the actions of a coagulase produced by *Y. pestis* and a trypsin-like enzyme present in the flea's stomach result in the formation of an infected clot that blocks the flea's proventriculus. In obstructing the flea's intestinal tract, the clot allows further replication of bacteria. When the flea tries to feed again, it regurgitates large numbers of plague bacilli. The formation and dissolution of the fibrin clot are temperature dependent. At temperatures greater

than 27°C (>80.6°F), a fibrinolytic enzyme is activated that dissolves the clot and allows the flea to dispose of the bacillus. One postulation is that this temperature-dependent phenomenon is responsible for the observed cyclic nature of urban plague epidemics, which tend to subside with the advent of hot weather.[7]

In contrast, fleas in which the intestinal tracts do not become blocked contribute to the endemicity of plague by harboring the organism and transmitting it in sublethal doses.[9] Sylvatic plague depends on the rodent flea as the vector. This flea, although not as efficient as the rat flea in transmitting the bacillus, may itself become a reservoir of *Y. pestis* by surviving for 12 to 15 months after the original host dies. In the new season, it reintroduces the plague bacillus into the new rodent population.[47] The observation that *Y. pestis* can survive in the soil during interepizootics suggests another possible mechanism of transmission of plague.[52]

EPIDEMIOLOGY

More recent studies have suggested that plague is an ancient disease of mammals; the plague bacterium emerged 1,500 to 20,000 years ago as a clone that evolved from *Y. pseudotuberculosis* that first caused outbreaks in Africa.[1] The plague bacillus exists in enzootic cycles involving wild animals or domestic rats. In urban plague, the course of events usually is initiated by the introduction of the plague bacillus from an enzootic focus into a susceptible rat population. With humans and rats living in proximity, an epizootic in rats may be followed by an epidemic in humans.[47] The epidemic may subside with the advent of hot, humid weather[7] or the obliteration of the rat population.[47] Such epidemics rarely occur today but have been described in the former South Vietnam[4,33] and more recently in India.[13] Between 1985 and 1999, 23 countries reported a total of 29,020 cases of plague to the World Health Organization, with an average mortality rate of 11 percent; major epidemics and outbreaks occurred in Tanzania (1991), Zaire (1992, 1993), Peru (1993, 1994), India (1994), and Madagascar (1995), with fatality rates ranging from 4.6 to 22.3 percent.[55]

In the United States today, humans become infected most frequently by direct contact with a sylvatic reservoir of infection. Sporadic human cases usually result from working or hunting in a plague-infested area[31] and increasingly from living near foci of infection as suburban spread encroaches on the natural habitats of rodents.[14] In recent years, domestic animals, especially cats, have been responsible for a significant proportion of human cases. During 1990 to 2005, 107 cases of plague were reported in the United States, a median of 7 cases a year. By September 2006, 13 plague cases, with two deaths (case-fatality rate, 15%), had been reported from four states (New Mexico, Colorado, California, and Texas). Such resurgences often occur after ecologic changes resulting in population increases in ground rodents such as prairie dogs, ground squirrels, mice, and rats in the American Southwest.[15]

Sylvatic plague epizootics occur in the summer. Most cases of rural plague occur between April and September. The rare occurrence of human plague in the winter usually is associated with hunting and direct exposure to infected tissues.[12,32,37]

The continental United States has a large enzootic focus that includes 130 counties in 15 western states. Surveillance for plague in rodents during the 1990s has identified infected animals farther east than ever before reported. The plague bacillus now has been isolated in wild rodents in eastern Montana, western Nebraska, western North Dakota, and eastern Texas.[14] Between 1925 and 1965, the number of reported cases in the United States averaged between two and three per year.[8,10] During the 1970s, 105 cases were reported.[32] The number of cases reported in 1980 through 1982 showed a similar increasing trend.[10] Between 1970 and 1979, 53 percent of cases were in females, in contrast to the period 1926 to 1969, when only 27 percent were in females. Approximately 60 percent of cases occur in individuals younger than 20 years.[32] Of 10 confirmed cases reported in the United States in 1993, however, the age distribution was 22 to 96 years. Five of the patients were older than 65 years.[14] Native Americans living on reservations in Arizona, New Mexico, and Utah are at increased risk. In the period 1970 to 1979, 35 percent of cases in these three states occurred in Native Americans.[10,32] Many of the patients were infected within 1 mile of their residence and almost all within their state of residence.[26] Seven of the 10 patients described in 1993 were exposed in their home sites, and one, a veterinarian, was exposed at work.[14]

Occasionally, plague has been acquired by a traveler in an endemic area who then traveled during the incubation period to a plague-free region of the country. This set of circumstances shows why all physicians need to be aware of the presenting symptoms and signs of plague and to obtain an accurate travel history.[34]

PATHOGENESIS AND PATHOLOGY

The portal of entry of the plague bacillus determines, to some extent, the form of disease. The most common portal of entry is the skin when it is bitten by an infected flea. Broken skin may provide access for direct inoculation while infected animals are being handled. After overcoming the skin barrier, the organisms move through the lymphatics to the regional lymph nodes, where they elicit an inflammatory response. The infection may be localized at this site, with subsequent formation of antibody and recovery. This clinical form is known as *pestis minor*. The bacillus commonly is disseminated through the bloodstream. Distant organ involvement may include the liver, spleen, kidneys, lungs, and meninges. Disseminated intravascular coagulation is common in fatal cases. Coagulation defects, including thrombocytopenia and elevated fibrin split products[4] and fibrin deposits in the glomeruli,[21,47] may be present. Bacteremia is not synonymous with severe disease and occurs commonly in mild cases.[47]

The major determinant of severity seems to be the presence of high levels of endotoxin. The toxin of *Y. pestis* has the biologic properties of typical endotoxin. When injected into experimental animals, it can cause the clinical symptoms and signs and pathologic changes characteristic of endotoxic shock and death. The quantity of

endotoxin necessary to kill is estimated to be comparable to that present in a lethal dose of live bacteria.[2,54] The murine toxin of *Y. pestis* has a direct inhibitory effect in vitro on the respiration of heart mitochondria of rats and mice, whereas it has little or no effect on the mitochondria of rabbits, chimpanzees, dogs, and monkeys. The differing sensitivities in vitro correlate with the susceptibilities in vivo of these species to *Y. pestis* infection.[50]

Achieving high levels of toxin depends on the ability of the bacillus to replicate in the infected host. Resistance to phagocytosis had been assumed to be related to virulence. More recent experimental evidence has shown that virulent *Y. pestis* organisms are phagocytosed, but, in contrast to avirulent ones, are not killed. They continue to replicate freely in macrophages, allowing the accumulation of endotoxin.[30,50]

When the lung is the portal of entry, the disease usually is more fulminant. After being inhaled, bacilli replicate freely in the alveolar spaces. Severe pneumonia, endotoxemia, and septicemia ensue and, if untreated, cause death. In fatal cases, the thoracic lymph nodes show infarction, necrosis, and liquefaction, with pus formation. Edema and inflammation of the surrounding tissue are common.[47] The mucosa of trachea and bronchi is covered by bloody, frothy exudate. Submucosal hemorrhages and areas of necrosis may surround the trachea. The pleural surfaces contain hemorrhagic lesions and fibrinous adhesions. The lung parenchyma may be consolidated or show signs of acute edema.[47] The predominant histologic feature is an alveolar exudate consisting of histiocytes and polymorphonuclear leukocytes.[21]

Other organs also are involved. The kidneys may appear grossly hemorrhagic and contain areas of necrosis. Microscopic examination reveals leukocytic infiltrates of congested veins and capillaries. Glomeruli with fibrin thrombi frequently are found in patients with disseminated intravascular coagulation.[21] Biopsy of purpuric skin lesions reveals subepithelial hemorrhages and fibrin deposit in the capillaries. These changes are indistinguishable from the changes seen in a generalized Shwartzman reaction.[4]

CLINICAL MANIFESTATIONS

The incubation period of *Y. pestis* generally is 3 to 4 days but ranges from a few hours to 10 days. The onset of illness usually is abrupt, beginning with fever, malaise, weakness, and headache.[47,48] Fever is high, frequently accompanied by shaking chills.[41] The appearance of a visible and palpable bubo may be preceded by pain and tenderness at that site.[48]

On physical examination, the patient is "toxic," apprehensive, and tachycardic. The inoculation site in the skin may not be evident, or it may be marked by a carbuncle. In bubonic plague, typical large, fixed, edematous, and exquisitely tender nodes are present at one anatomic site.[33] In decreasing order of frequency, the areas of nodal involvement are the groin (including femoral and inguinal nodes), axilla, and neck.[47] Any lymph node may suppurate, sometimes presenting an atypical picture (e.g., if intra-abdominal nodes are involved, an acute abdominal emergency may be suspected).[48] Septicemia as an initial presentation of *Y. pestis* infection is common.[26] Twenty-five percent of the patients presented without adenopathy in the 71 confirmed cases of plague in New Mexico from 1980 to 1984. All patients with septicemic presentation had fever and chills, and most had tachycardia, tachypnea, and relative hypotension. Seventy-two percent had gastrointestinal symptoms. Plague pneumonia was twice as likely to occur among septicemic patients as among patients with bubonic plague. Septicemic patients were significantly older and more likely to die than were patients with a bubonic presentation. Although septicemic plague occurred more often in older patients, patients younger than 30 years with septicemic presentation were more likely to die.[26]

As a result of its nonspecific presentation, septicemic plague is difficult to diagnose early. Of 27 patients with plague admitted to Indian Medical Center in Gallup, New Mexico, between 1965 and 1989, 5 had a nonspecific febrile syndrome with upper respiratory tract symptoms. They were prescribed penicillin. Three of the 5 patients died. Another 5 patients had a nonspecific febrile syndrome associated with chills, myalgias, and anorexia. These patients were not treated initially with antibiotics, and 3 died.[18] The index of suspicion must be high because early diagnosis is imperative for avoiding a high risk of mortality. Individuals who appear to have what seems to be community-acquired, gram-negative sepsis and who reside in or have a history of recent travel to endemic areas of plague must be evaluated for and treated with antibiotics effective against *Y. pestis*.[39]

Gastrointestinal symptoms occur in patients with plague, especially patients with septicemic plague.[25] Between 1980 and 1984, more than half of the 71 patients with plague in New Mexico had gastrointestinal symptoms that sometimes preceded the appearance of the buboes in the bubonic cases. Common symptoms are abdominal pain, nausea, vomiting, and diarrhea. These symptoms are believed to be a general response of the body to gram-negative septicemia. Occasionally, hepatosplenomegaly and mesenteric or retroperitoneal lymphadenopathy have masqueraded as an acute abdomen.[27]

Neurologic manifestations caused by the effects of toxin on the brain are common. A patient with plague may have insomnia, delirium, stupor, weakness, staggering gait, vertigo, disorders of speech, and loss of memory.[38] *Y. pestis* meningitis is a rare occurrence, but it does occur. Children younger than 15 years old seem to be more susceptible, and septicemic patients are four times more likely to develop meningitis than are patients with bubonic plague.[42] It often manifests while the patient is well into a course of antibiotic therapy for bubonic or septicemic plague.[3] When intravascular coagulation supervenes, renal involvement may manifest as acute cortical or tubular necrosis. Hepatic involvement may be evidenced by mildly elevated liver enzymes.[47] Hantavirus pulmonary syndrome may mimic septicemic or pneumonic plague; both share a similar geographic distribution, and patients for whom this diagnosis is contemplated should be treated with antibiotics to cover the possibility of plague.[45]

Primary pneumonic plague has identical constitutional symptoms but follows a fulminant course with a more

pronounced pulmonary component. Within 20 to 24 hours after the onset of the illness, tachypnea, dyspnea, and cough productive of bloody mucopurulent sputum supervene. If early and effective treatment is not instituted, the patient usually dies.[47]

DIFFERENTIAL DIAGNOSIS

Because of the rare incidence of plague today, the diagnosis often is delayed or missed. Bubonic plague may be confused with other diseases affecting the skin and lymph nodes. The diagnosis of staphylococcal or streptococcal adenitis can be established easily by culture. Lymphogranuloma venereum is more indolent, has milder systemic symptoms, and is associated with anogenital ulcer. Syphilitic adenitis usually is nontender. With cat-scratch disease and *Pasteurella multocida* infections, the constitutional symptoms are few and the patient typically has a history of animal exposure. Tularemia has a more gradual onset.[47] In their later stages, the ulcerated skin lesions of plague may resemble anthrax.[33]

DIAGNOSIS

The most important factor in promptly establishing the diagnosis of plague is having a high index of suspicion. Suspicion should trigger immediate notification to the local or state health department. The state reference laboratory can arrange for rapid diagnostic tests.

Bacterial staining of lymph node material by Giemsa, Wayson, or Wright stain often shows the typical bipolar plague organisms. In the septicemic form of the disease, similar bacterial staining of venous blood frequently permits visualization of the plague bacillus.[36] Fluorescent antibody staining of direct smears and tissues may provide a rapid, presumptive diagnosis of plague.[28] More recent rapid tests, such as enzyme-linked immunosorbent assay for F1 antigen[16] or the polymerase chain reaction for F1 antigen genes (*pla* and *caf1*), have shown promise in the laboratory or in outbreaks, but they are not widely available.[12]

TREATMENT

Therapeutic decisions cannot await culture results. All patients suspected of having plague should receive prompt antimicrobial therapy after appropriate blood and tissue samples have been obtained for cultures, fluorescent antibody staining, and serologic testing.

The sulfonamides and streptomycin proved effective when they were introduced first in the 1940s. Resistant strains to one or the other of these antibiotics soon appeared.[6,49] Despite the paucity of published trials in humans on antibiotic effectiveness, other than streptomycin and tetracycline, the Working Group on Civilian Biodefense Consensus Statement[28] recommends gentamicin as an effective alternative to streptomycin for patients needing parenteral antibiotics. Gentamicin has been used frequently in recent years and has shown comparable outcomes to streptomycin in one case series.[3,5] In vitro and in vivo studies in mice corroborate its effectiveness against *Y. pestis* infections.[53,59]

For acutely ill patients thought to have plague infection, streptomycin and gentamicin are the drugs of choice. If available, streptomycin is given intramuscularly, 20 to 30 mg/kg/day in two divided doses up to a maximum of 1 g every 12 hours.[38] Gentamicin is administered intravenously or intramuscularly, 7.5 mg/kg/day to children and 3 to 5 mg/kg/day to adults in three divided doses. Although single daily doses of gentamicin are commonly recommended today and may be effective in infections due to *Yersinia pestis*, they have not been studied to date. Antibiotic susceptibility testing should be done because *Y. pestis* plasmid-mediated, multiple-antibiotic resistance has been described.[23]

When plague meningitis develops, chloramphenicol, 50 to 100 mg/kg/day (after administration of an initial dose of 25 mg/kg) intravenously in four divided doses (the maximal dose for chloramphenicol is 4.0 g/day), is the treatment of choice. Duration of therapy is determined by the length and severity of the illness. Treatment is continued for at least 7 days in patients with uncomplicated disease.[13]

Patients older than 8 years of age who do not require hospitalization receive tetracycline at a dose of 25 to 50 mg/kg/day every 4 to 6 hours up to a total daily dose of 1 g in children and 2 g in adults. When outpatient treatment is given, the patient should be observed closely for the first 3 days to ensure resolution of the disease.[13] Sulfonamides may be used for prophylaxis in pediatric patients as an alternative to the tetracycline class of antibiotics.[28] Doxycycline at a dose of 4 mg/kg/day (up to a maximum of 200 mg) divided into two doses may be substituted for tetracycline.

PROGNOSIS

In outbreaks of untreated plague, the mortality rate has ranged from 40 to 70 percent. Pneumonic plague almost invariably is fatal without treatment. With prompt specific antimicrobial therapy, the overall mortality rate for plague has decreased to 5 percent.[35] Complications during convalescence include polyarthritis, small lung abscesses, delayed suppuration of buboes,[33] and meningitis. *Staphylococcus aureus* and *Pseudomonas* spp. may superinfect involved lymph nodes.[48] Immunity usually ensues after clinical or asymptomatic infection occurs, but natural reinfection rarely has been observed.[48]

PREVENTION AND CONTROL

Institution of hygienic measures and eradication of rats from areas of human habitations have all but eliminated epidemics of urban plague. When epizootics occur in wild rodents, control measures must be directed against rodents and fleas. Vector control can be achieved by the use of insecticides in fields and housing areas. In plague-endemic areas, the public must be instructed to avoid burrows, not to handle sick or dead rodents, to de-flea household pets, and to eliminate trash near living areas.[10]

The immune status of domestic animals can be used as a surveillance tool to ascertain the presence of *Y. pestis* in the community. Dogs, cats, and swine develop antibodies to the fraction 1 antigen of *Y. pestis*.[29,41]

Patients with plague should be isolated with respiratory precautions until they are bacteriologically sterile. Contacts of patients with pneumonic plague should receive chemoprophylaxis with tetracycline at 25 to 50 mg/kg/day up to 2 g in adults and up to 1 g in children 8 years and older. Younger children receive trimethoprim-sulfamethoxazole at 40 mg/kg/day (sulfamethoxazole) in two equal doses orally.[29] The 6-day quarantine period for international travel for contacts of patients with plague does not guarantee the clearance of the bacillus from asymptomatic pharyngeal carriers.[6] Public and professional education in endemic zones is paramount for ensuring prompt reporting of human and animal cases.[52]

Plague vaccines had been used since the late 19th century for individuals at high risk for occupational exposure. They are no longer being manufactured in the United States. Research in this area is continuing.[28,58]

CHAPTER 113

Other *Yersinia* Species

Charles R. Woods, Jr.

Yersinia spp. are gram-negative, coccobacillary organisms that are primarily zoonotic. The genus is a member of the family Enterobacteriaceae and consists of 11 species, 3 of which clearly are human pathogens[74]: *Yersinia pestis*, *Yersinia pseudotuberculosis* (both formerly included in the genus *Pasteurella*), and *Yersinia enterocolitica*. *Y. pestis*, the causative agent of plague, is found in rodents and insect vectors and is discussed in Chapter 112.

Y. enterocolitica and *Y. pseudotuberculosis* are responsible for a variety of syndromes, some of which originally were called *pseudotuberculosis*. Infections caused by these primarily enteropathogenic *Yersinia* spp. now are collectively referred to as *yersiniosis*, which is the focus of this chapter. Molecular phylogenetic analysis suggests that *Y. pestis* evolved from *Y. pseudotuberculosis* 1500 to 20,000 years ago.[4] The genomes of representative strains of the three pathogenic *Yersinia* spp. have been sequenced.[213]

During the past 3 decades, *Y. enterocolitica* has been recognized as an important human pathogen worldwide and is a common cause of gastroenteritis in some pediatric populations of the industrialized world.[1,50,61,127] *Y. enterocolitica* also has drawn attention because of its immunologic or postinfectious manifestations, which include reactive arthritis and erythema nodosum.[50] *Y. pseudotuberculosis*, although widespread, is a much less common cause of human disease.[74] In Japan, it has been associated with clinical illness that sometimes has resembled Kawasaki disease.

HISTORICAL ASPECTS

In 1883, Malassez and Vignal[140] described a bacterium that produced a disease they named *pseudotuberculosis*. When injected into guinea pigs, the organism produced tuberculosis-like lesions. It grew at 4° C (39.2° F) and multiplied better at 22° C (71.6° F) than at 37° C (98.6° F). This observation was confirmed in 1910 by Albrecht,[11]

who labeled the disease *enteritis follicularis suppurativa*. The first case of mesenteric adenitis, the most common syndrome produced by *Y. pseudotuberculosis*, was reported in 1913 by Saisawa.[187] A second instance of disease that indicated its capacity to produce death (i.e., bacteremia and multiple hepatic abscesses) was recorded in 1949 by Hassig and colleagues.[86] Masshoff[142] was the first to recover the organism from a culture of mesenteric lymph nodes of a patient with the clinical picture of acute appendicitis. Masshoff and Dolle[143] subsequently described the histologic picture produced by *Y. pseudotuberculosis*. In 1954, Knapp and Masshoff[115] first reported the clinical features of infection produced by this organism. Only 14 cases of this infection had been described up to that time.[60]

The existence of a species of *Yersinia* other than that causing pseudotuberculosis was suggested in 1933 by Gilbert,[67] who reported an unusual infection in animals. Schleifstein and Coleman[188,189] examined numerous organisms isolated between 1933 and 1957 from stool cultures of human cases of diarrhea from which *Salmonella* and *Shigella* organisms could not be recovered and that resembled the infections in animals reported by Gilbert. These investigators identified an organism that had not been described previously and named it *Bacterium enterocoliticum*. In 1964, it was named *Y. enterocolitica* by Frederiksen.[64]

The genus is named for A. J. Yersin, the French bacteriologist who first isolated the plague bacillus.[203] During the past 40 years, an extensive literature detailing the microbiology, pathology, epidemiology, molecular pathogenesis, and clinical features of disease caused by *Y. pseudotuberculosis* and *Y. enterocolitica* has accumulated.*

MICROBIOLOGY

Yersinia organisms are large (0.5 to 1 μm × 1 to 2 μm or larger), gram-negative, and ovoid or rod-shaped. *Y. enterocolitica* and *Y. pseudotuberculosis* are motile at 22° to 25°C (71.6° to 77°F) but not at 37°C (98.6°F). Similar to other members of Enterobacteriaceae, *Yersinia* organisms are facultative anaerobes and grow well on ordinary media. On Gram staining, *Y. pseudotuberculosis* appears as a large coccobacillus. Staining with methylene blue and carbol fuchsin discloses a bipolar (safety pin) morphology of most, but not all, strains. *Y. enterocolitica* is smaller and shows little, if any, bipolarity.[200,203]

Yersinia organisms may be confused with coliforms, such as *Morganella*, *Proteus*, *Shigella*, *Salmonella*, and *Providencia* spp., or *Escherichia coli* or with *Y. pestis* or *Brucella*, and *Achromobacter* organisms, unless careful biochemical and physiologic studies are conducted. *Yersinia* organisms reduce nitrates and are oxidase-negative, catalase-positive, urease-positive, and citrate-negative. They ferment glucose, maltose, mannitol, glycerol, xylose, and fructose, producing acid but no gas with each sugar. *Yersinia* organisms usually do not ferment lactose but produce α-galactosidase. They do not ferment dulcitol, inositol, raffinose, or rhamnose. On lysine-iron agar slants, *Yersinia* organisms produce an alkaline slant with an acid butt. They do not produce hydrogen sulfide. The Voges-Proskauer reaction is negative at 37°C (98.6°F) but may be positive at 25°C (77°F) for some strains of *Y. enterocolitica*. All strains of *Y. pseudotuberculosis* and most strains of *Y. enterocolitica* isolated in Europe are indole-negative. Most strains of *Y. enterocolitica* found in the United States have been indole-positive.*

Although these two species of *Yersinia* share many properties, they are distinguishable on the basis of several biochemical activities, antigenic structure, and sensitivity to various *Yersinia* phages.[184] *Y. enterocolitica* produces an acid slant and acid butt on triple sugar iron agar caused by fermentation of sucrose, whereas *Y. pseudotuberculosis* produces an alkaline slant and an acid butt. *Y. enterocolitica* elaborates ornithine decarboxylase and ferments sucrose and amygdalin. *Y. pseudotuberculosis* does none of these, but it ferments adonitol, which *Y. enterocolitica* does not.[95,203]

Commercially available tests used to identify Enterobacteriaceae in clinical laboratories may not contain the biochemical reactions needed to identify specific *Yersinia* spp. Traditional macroscale biochemical testing may be required to distinguish *Y. enterocolitica* and *Y. pseudotuberculosis* from nonpathogenic *Yersinia* spp.[80,131] On solid culture media, colonies of the pathogenic species typically are small, smooth, opaque colonies. The colonies of nonpathogenic species are larger and more translucent.[109] The emerging bacterial identification method, matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry, appears reliable for distinguishing *Yersinia* isolates at the species level.[205]

Genomes and Typing of *Yersinia* Strains

Biotyping and serotyping have been the predominant methods used to characterize strains of *Y. enterocolitica*. At least 54 to 60 serotypes of *Y. enterocolitica* exist on the basis of variability of somatic O antigens, but only 11 typically are associated with human disease.[24,26,61,74,216] Six biotypes of *Y. enterocolitica*, designated 1A, 1B, and 2 to 5, have been defined on the basis of differences in the following: lipase activity; salicin acid production; esculin hydrolysis; indole production; ornithine decarboxylase; Voges-Proskauer test; pyrazinamide activity; nitrate reduction; and fermentations of xylose, trehalose, sorbose, and inositol.[26,36,215]

Biotypes 1A, 2, 3, 4, and 5, now designated as *Y. enterocolitica* subsp. *palearctica*, are considered generally low pathogenic.[194] Biotype 1B, now designated as *Y. enterocolitica* subsp. *enterocolitica*, is considered highly pathogenic. Further subspecies distinctions may be forthcoming.[195] The genomes of biotypes 1A, 1B, and 2 to 5 are about 4.9, 4.6, and 4.5 Mb, respectively.[177] Genomic size differences are primarily related to number and distribution of insertion sequences.

Only a few serotype:biotype combinations are regarded as human pathogens: O:8, O:4, O:13a,13b,

*References 14, 24, 26, 28, 48, 50, 58, 60, 88, 89, 94, 100, 113-116, 127, 135, 147, 183, 200, 202, 207, 219, 232.

*References 53, 71, 95, 157, 164, 200, 203.

O:18, O:20, and O:21 (biotype 1B); O:9 and O:5,27 (biotype 2); O:1,2,3 and O:5,27 (biotype 3); O:3 (biotype 4); and O:2,3 (biotype 5).[221] These pathogenic strains, which carry *Yersinia* virulence plasmids (pYV), generally have negative test results for pyrazinamidase activity, esculin hydrolysis, and salicin fermentation. Nonpathogenic strains, generally of biotype 1A, have positive test results for each of them.[44,51,107] Data suggest that some biotype 1A strains that lack pYV and other *Yersinia* virulence factors also may cause gastroenteritis.[73,194,196]

Strains of *Y. enterocolitica* can be typed genetically by multilocus sequence typing (MLST),[195] repetitive element-based (interrepeat) polymerase chain reaction (PCR), pulsed-field gel electrophoresis,[152] and ribotyping.[132] These methods allow distinction among strains within biotypes and serotypes and may be useful for outbreak and other epidemiologic investigations.

The complete genomes of the "Old World" biotype 3/O:9 strain 105.5R(r), prototypical of isolates common in Europe and Japan, and "New World" biotype 1B/O:8 strain 8081, prototypical of isolates in China, have been compared. The type III secretion systems differ, and strain 8081 has lost ancestral clusters of genes that contribute to enteric survival and pathogenesis.[226] Other genomic studies have shown that low pathogenic *Y. enterocolitica* subsp. *palearctica* biotype 4/O:3, which causes sporadic human disease and commonly colonizes pigs worldwide, also possess a type III secretion system and other alternative virulence determinants in contrast to the high pathogenic *Y. enterocolitica* subsp. *enterocolitica* (biotype 2) strains associated with outbreaks of human disease in Northern Europe.[17]

At least 11 antigenic groups of *Y. pseudotuberculosis* exist on the basis of variation of somatic O antigens. They have been labeled 1a, 1b, 2a, 2b, 2c, 3, 4a, 4b, 5a, 5b, and 6.[77,99,139] Type 2 is related antigenically to *Salmonella* group B, and type 4 is related to *Salmonella* groups D and H.[71] Two clusters of *Y. pseudotuberculosis* have been described using MLST. Strains of one cluster are distributed worldwide and usually harbor pYV. The second cluster lacks pYV and is currently restricted to the Far East.[43]

EPIDEMIOLOGY

Although most of the early reports of yersiniosis caused by *Y. pseudotuberculosis* and *Y. enterocolitica* came from northern Europe, these microbes have been identified with increasing frequency in all parts of the world,[13] with the possible exception of South America. *Y. enterocolitica* infections are more common in the United States than *Y. pseudotuberculosis*. Between 1996 and 2007, 1355 cases of foodborne *Y. enterocolitica* infections were identified by FoodNet in contrast to only 18 cases of foodborne *Y. pseudotuberculosis*.[134] The median ages of infected persons were 6 years (0 to 94 years) and 47 years (16 to 86 years), respectively.

During 1996 to 2009, FoodNet data show the rate of foodborne disease caused by *Y. enterocolitica* in the United States was stable at 0.5/100,000 population.[160] Rates have been highest in blacks but declined from 3.9 to 0.4/100,000 during this time period. The rate in Black children less than five years old declined from 41.5 to 3.9 per 100,000.

Yersinia enterocolitica

Y. enterocolitica is distributed worldwide but is isolated most frequently in cooler climates.[148] Whether such geographic differences reflect differences in reservoirs or culinary practices that may enhance the risk for acquisition of this organism, or rather represent differences in surveillance for the disease and use of more sensitive culturing techniques in these areas, is unclear.[50] Increased frequency of infections during fall and winter has been reported from Europe[192] and the United States,[1] but no seasonality is evident among outbreaks of disease in which more than three cases of *Y. enterocolitica* disease have been identified.[50]

Geographic differences in serotype distribution and frequency also exist. Sporadic infections caused by biotype 4/serotype O:3 and biotype 3/serotype O:9 strains are common in Europe,[9,93] but outbreaks rarely have occurred.[50] In North America, multiple serotypes have been responsible for sporadic disease,* but more recently serotype O:3 has become predominant.[36,54,127] Five outbreaks in the United States have been caused by serotype O:8, and two outbreaks in Canada have been caused by serotypes O:5 and O:5,27.[50] Disease caused by serotype O:8 has been reported in Europe.[93] Biotype 2/serotype O:9 is predominant in China.[226]

The true incidence and prevalence of *Y. enterocolitica* infection are unknown.[50] The reported proportional frequency of isolation of *Y. enterocolitica* from stool cultures from patients with diarrhea has ranged from 0 to 3.2 percent in series from Europe, the United States, and New Zealand (Table 113-1).† Symptomatic infection occurs more commonly in children. Most series show a slight male predominance of approximately 1.3 : 1.[54,61,141,215] Surveillance at five FoodNet sites in the United States during 1996 to 1999 found that African-American infants had far higher rates than white infants, with a peak occurrence from November to February (Fig. 113-1).[174]

Animals and water sources are the primary environmental reservoirs for *Y. enterocolitica*, but the biotypes and serotypes of the strains found in them usually differ from those causing human disease.[36,50,192] Blood transfusions also may be a source of *Y. enterocolitica* infection.[37]

Animal Reservoirs

Y. enterocolitica strains have been isolated from a wide variety of mammals (i.e., dogs, pigs, sheep, rabbits, guinea pigs, cows, horses, chinchillas, and monkeys), frogs, fish, flies, fleas, snails, crabs, and oysters. Birds do not seem to be a major reservoir for *Y. enterocolitica*, although avian isolates have been reported.[50,95,135] The proportion of enteric illness attributable to animal contact in the United States in recent years is 1 percent.[79]

TABLE 113-1 **Percentage of Stool Cultures Yielding *Yersinia Enterocolitica***

Country	Years	Population	Total Cultures	Percentage *Y. Enterocolitica*
Canada[141]	1977-1978	Symptomatic children	6364	2.8
The Netherlands[92]	1982-1984	Enteritis patients <40 yr	827	2.9
Italy[146]	1981-1985	Children with diarrhea	2500	1.4*
New Zealand[61]	1988-1993	Patients with gastroenteritis	231,128	0.6
U.S. (Detroit, MI)[52]	May-November 1977	Children with diarrhea	1262	0
U.S. (New York State)[192]	1976-1980	Survey of cultures from a state laboratory, six hospitals, and several daycare centers	2487	0.9†
U.S.‡ (7 cities)[127]	November 1989-January 1990	All stool cultures submitted to seven hospitals	4841	0.8
U.S. (St. Louis, MO)[112]	1998-2001	Children presenting to an emergency department with diarrhea	1626	0.1

*Yearly percentages during the 5 years ranged from 0 to 4.4 percent.
†This increased to 4 percent of 3035 isolates when cultures from an outbreak and other screenings were included.
‡Includes Detroit, MI.

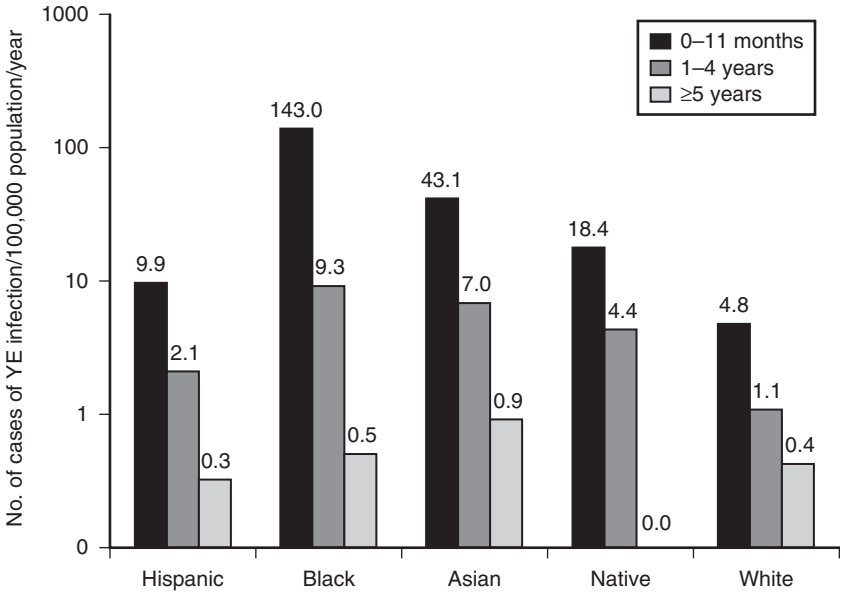

FIGURE 113-1 ■ Adjusted incidence of *Yersinia enterocolitica (YE)* infection, by race and age. Average incidences are given over the 4-year surveillance period (1996 to 1999) by age group and adjusted race/ethnicity. (From Ray SM, Ahuja SD, Blake PA, et al. Population-based surveillance for *Yersinia enterocolitica* infections in FoodNet sites, 1996-1999: higher risk for disease in infants and minority populations. *Clin Infect Dis* 2004;**38**:S181-9.)

Pigs seem to be an important reservoir for the human pathogenic serotypes O:3 and O:9 in Europe and Japan and serotype O:3 in North America and South Africa.[50,127,170] The biochemical and phage typing profiles of isolates from pigs are similar to those of strains commonly responsible for human infections.[219] *Y. enterocolitica* has been isolated from the tongue, tonsils, and cecal contents of swine and from pork, ham, and butcher shop cutting boards.[50,71] Pig farmers in Finland were 3 times and 2.4 times as likely to have seropositivity to serotypes O:3 and O:9 than were berry farmers.[191]

Wild rodents captured in areas of Japan where human infections caused by *Y. enterocolitica* serotype O:8 had occurred were shown to harbor isolates of the same serotype.[46] Two distinct serotype O:8 strains, defined by restriction enzyme analysis of the virulence plasmids, were isolated from humans and rodents. This finding suggests that rodents are a potential source of sporadic human infection in Japan.

Apparent transmission to humans from dogs and cats also has been reported. A fecal-oral or oral-oral route has been postulated but not confirmed. Little evidence supports airborne or insect vector–borne transmission.[50]

Foods and Water

In countries with high numbers of cases of yersiniosis, ingestion of raw pork has been common. Infection with serotypes O:3 and O:9 was highly associated with ingestion of raw pork during the 2 weeks preceding the illness in a case-control study.[211] In Belgium, laboratory surveillance that began in 1967 showed yearly increases in cases through 1986. After a media campaign was launched to dissuade people from eating raw or undercooked pork or pork products and to educate consumers regarding good hygiene practices during food preparation, the number of isolations of *Y. enterocolitica* decreased from a high of 1469 in 1986 to 707 in 1996.[221] Still, eating raw minced

pork or other foods prepared from raw pork products remains an ongoing risk factor for *Y. enterocolitica* infection for young children in several European countries.[23,97,182] Changes in techniques for slaughtering may have contributed to this decline. Preparation of chitterlings in the household was a risk factor for *Y. enterocolitica* infection among children in Michigan[1] and Illinois.[38]

Ingestion of water contaminated with serotype O:8 has led to sporadic cases and outbreaks.[50] Water and malnutrition have been associated with clinical illness in Gaza.[57] Bean sprouts that had been immersed in contaminated water were the source of an outbreak in Pennsylvania in 1982. Ingestion of tofu (bean curd) packed in untreated spring water that subsequently was found to be contaminated with *Y. enterocolitica* caused 44 cases of symptomatic infection in Washington state in 1981 and 1982.[209] Serotypes commonly found in water samples rarely are isolated from humans with symptomatic disease, however.[36]

Contaminated milk has been implicated as the source of several large outbreaks of *Y. enterocolitica* infection.[20,50,216] Whipped cream and ice cream may harbor the organism. Contamination of milk products after pasteurization has been documented. *Y. enterocolitica* has been found in raw milk samples from cows and goats. Samples of beef, lamb, poultry, oysters, and a variety of vegetables also have been found to be contaminated with *Y. enterocolitica*.[33,50,71]

Serotypes O:3, O:4,33, O:5,27, O:7,8, O:8, O:10, O:13, and O:16 cause most human disease in North America but rarely are isolated in surveillance of water or food samples. Serotype O:8 strains have been cultured from cattle, milk, and water samples[157]; serotype O:4,33 strains have been isolated from pigs and cattle; and serotype O:4,32 strains have been found in cheese, ham, sausage, raw beef, and one pancake specimen.[36,192,216]

Incubation, Carriage, and Transmission in Humans

The incubation period of *Y. enterocolitica* enterocolitis ranges from 1 to 14 days, with a median of approximately 4 days.[36,50,127] The minimal infective dose of *Y. enterocolitica* is unknown. Ingestion of 3.5×10^9 organisms by a volunteer resulted in diarrhea in less than 1 day, but such large inocula are unlikely to be encountered clinically. The duration of excretion of the organism after development of infection in children ranges from 14 to 97 days (mean 42 days).[141] The impact, if any, of antibiotic treatment on the duration of carriage is unknown.

Transmission to household members occurs uncommonly, even among young children, who are at higher risk for development of symptomatic disease.[20,141,209] Six percent of household contacts developed disease in one outbreak,[209] but several large outbreaks with no secondary household cases have been reported.[50]

Yersinia enterocolitica *and Blood Transfusion–Related Sepsis*

In this era of screening for viral infections in blood donations, bacterial sepsis has become the most frequent infectious complication of blood transfusions in developed countries. Sporadic cases of *Y. enterocolitica* sepsis related to contamination of transfusions of red blood cells (RBCs) have been recognized since 1987 and have occurred in the United States, Europe, and Australia.[37,75] *Y. enterocolitica* is the most common cause of transfusion-related sepsis.[105] Rapid-onset septic shock, fever, chills, and atypical signs such as explosive diarrhea are common. Case fatality is about 50 percent.[45,75]

In many cases of transfusion-related sepsis, the contaminated RBC units had been stored for 25 days or more.[87] After experimental inoculation of small numbers of *Y. enterocolitica* into packed cells kept at 4°C (39.2°F), the organisms continue to replicate, reaching concentrations of 100 colony-forming units (CFU)/mL in 7 days and 10^6 CFU/mL in 21 days. This lag of 1 to 3 weeks in rapid growth is consistent with the increasing iron stores released from hemolyzing RBCs during storage. *Y. enterocolitica* multiplication is supported by glucose and adenine, which are part of RBC anticoagulant and additive solutions. Although growth is calcium-dependent during human infection at body temperatures, *Y. enterocolitica* can replicate in calcium-free media (e.g., RBCs anticoagulated via citrate chelation) at temperatures less than 30°C (86°F).[75] High levels of endotoxin can result from bacterial replication in RBC products and have been documented in samples from RBC units that led to transfusion-related sepsis.[45] Timely administration of effective antimicrobial agents appears to improve outcomes, suggesting a significant contribution from viable microbes.[75]

Human Outbreaks

Outbreaks of *Y. enterocolitica* disease have involved communities, families (with interfamily spread), hospitals, and schools. The sources of the organism have been various foods and animals, especially dogs. A review of these outbreaks suggests that infection may occur more commonly than has been recognized. Yersiniosis also resembles disease caused by *Salmonella* and *Shigella* organisms in many respects, including the environmental sources of the organisms, the clinical syndromes, and the occurrence of asymptomatic infection.

Outbreaks in Schools and Communities. A community outbreak caused by a serotype O:8 strain occurred in New York State in 1976.[19] At least 222 children and employees had a yersiniosis-like illness during a 10-week period. Illness was associated with drinking chocolate milk that was contaminated after pasteurization during hand mixing with chocolate syrup. Transmission of infection from ill children to household contacts was not observed. School-related outbreaks also have occurred in Japan.[15,234]

In the summer of 1982, thousands of individuals in several southern states who consumed milk from a single dairy developed yersiniosis. A total of 172 culture-positive infections were confirmed, many as a result of hospitalization for illness. Seventeen patients underwent appendectomy; 24 others had extraintestinal spread of infection. The strain involved was designated serotype O:13a,13b.[216] An outbreak associated with consumption of pasteurized

milk in Vermont and New Hampshire in 1995 probably resulted from contamination after pasteurization with a serotype O:8 strain, possibly from rinsing bottles with untreated well water.[5]

During November to December 2002, nine infants in the Chicago area developed gastroenteritis caused by *Y. enterocolitica*. Eight were African-American and were exposed to caretakers who had prepared chitterlings for holiday meals. All recovered, although six were hospitalized for a median of 5 days.[38]

Family Epidemics. In North Carolina, 21 individuals from four families were involved in an outbreak of yersiniosis that had an unusually high attack rate.[76] Of the 21 affected individuals, 18 were children 3 to 13 years of age; 16 of the 21 had diarrhea and fever, and 5 were asymptomatic. *Y. enterocolitica* was recovered from the spleen of the youngest child at autopsy. The diagnosis was established serologically in the others. A dog that had given birth to puppies that died of a diarrheal illness a week before the families became ill seemed to be the source of the infection.

Nosocomial Outbreaks. A young child who was hospitalized in Finland with acute gastroenteritis was the source case of infection in a housekeeping worker and four nurses who cared for her.[214] The infecting strain was serotype O:9. Another hospital outbreak involved nine patients in Canada.[173] It was caused by a serotype O:5 strain. Person-to-person contact was considered the likely mode of transmission.

Prevention of Disease

During outbreaks, efforts should be made to identify environmental sources and vehicles of transmission.[50] A single environmental source can harbor multiple serotypes of *Y. enterocolitica*, such that resulting outbreaks may be polyclonal.[209] Enteric precautions should be used for hospitalized patients with diarrhea caused by *Y. enterocolitica* (as with other causes of gastroenteritis).[50] At the population level, decreased consumption of raw or undercooked pork products potentially can reduce the incidence of infection.[211,221]

Yersinia pseudotuberculosis

Y. pseudotuberculosis may infect individuals of all ages, but at least 75 percent of patients with clinically apparent disease are children younger than 15 years of age.[99,184] Infection in young infants has been reported.[99,228] Of 130 cases diagnosed in Great Britain from 1959 to 1970, boys were involved three times more frequently than girls.[135] Infections occur more commonly during the cold months of the year.[99,185] The seasonal winter peak of human infection produced by *Y. pseudotuberculosis* is similar to that seen in wild and domesticated animals.[113,114,184]

The attack rates for children living in rural and urban areas seem to be the same. *Y. pseudotuberculosis* occasionally has been recovered from healthy individuals. Exposure to the organism seems to be uncommon; antibody to *Y. pseudotuberculosis* was detected in only 1/2000 sera samples from individuals with no history of yersiniosis.[64,184]

Y. pseudotuberculosis is distributed worldwide in a large variety of animals and birds, but infection seldom occurs.[68] Guinea pigs, rodents, and rabbits are infected most often[135] and may experience a plaguelike illness.[68,95] Lesions in guinea pigs may be confused easily with lesions caused by *Y. pestis*. Rats and other rodents also may have plaguelike disease caused by *Y. pseudotuberculosis*. The microbe can be cultured from tongue, tonsils, intestines, and large organs of infected animals.[156]

Infection has been reported in various domestic animals (i.e., cattle, sheep, goats, cats, dogs, hamsters), commercially raised fur bearers (chinchillas, mink, coypu), and other wild or captive animals (rabbits, raccoons, foxes, deer, beavers, monkeys, puma, kangaroos). *Y. pseudotuberculosis* has been found in more than 50 species of birds,[82,108,135] and epizootics have occurred among turkeys, ducks, pigeons, and doves and in aviaries of canaries and finches. Strains obtained from animals and birds in the United States are predominantly of serotypes 1a, 1b, and 3.[135,184]

The incubation period for human disease ranges from 41 hours to 20 days.[99] In a food-associated outbreak in Finland, the median incubation period was 8 days (Fig. 113-2).[102] The organism can survive in fresh tap water for 46 days at room temperature and for 8 months at 4° C (39.2° F). It can survive at 4° C in meat for 145 days and in milk and bread for 2 to 3 weeks.[135]

A family outbreak of mesenteric adenitis caused by *Y. pseudotuberculosis* that involved four siblings aged 7 to 14 years has been reported.[172] A pet dog was shown to have increasing antibody titers at the time the children were ill.

Periodic outbreaks have been reported in Japan, northern Europe, and areas of the former Soviet Union. Sandwiches prepared by a single bakery were the primary risk factor for 67 cases that occurred in a 3-week period in Japan.[99] Drinking unchlorinated well water or mountain stream water has been the source of other outbreaks. Children were much more likely to have clinical disease than adults. More recent outbreaks in Finland have been associated with contaminated lettuce and grated carrots.[102]

PATHOLOGY

The diseases produced by *Y. enterocolitica* and *Y. pseudotuberculosis* are similar and share the histopathologic theme of involvement of the lymphoid tissues of the intestinal mucosa and mesentery.

Yersinia enterocolitica

Y. enterocolitica infection predominantly affects the gastrointestinal tract. The most severe clinical symptoms correlate with an acute terminal ileitis. The mucosal surface of the ileum and other involved sites may be inflamed diffusely. Ulcerations may occur throughout the gastrointestinal tract and may be small and superficial or extend to the muscularis propria. Mucosal and submucosal

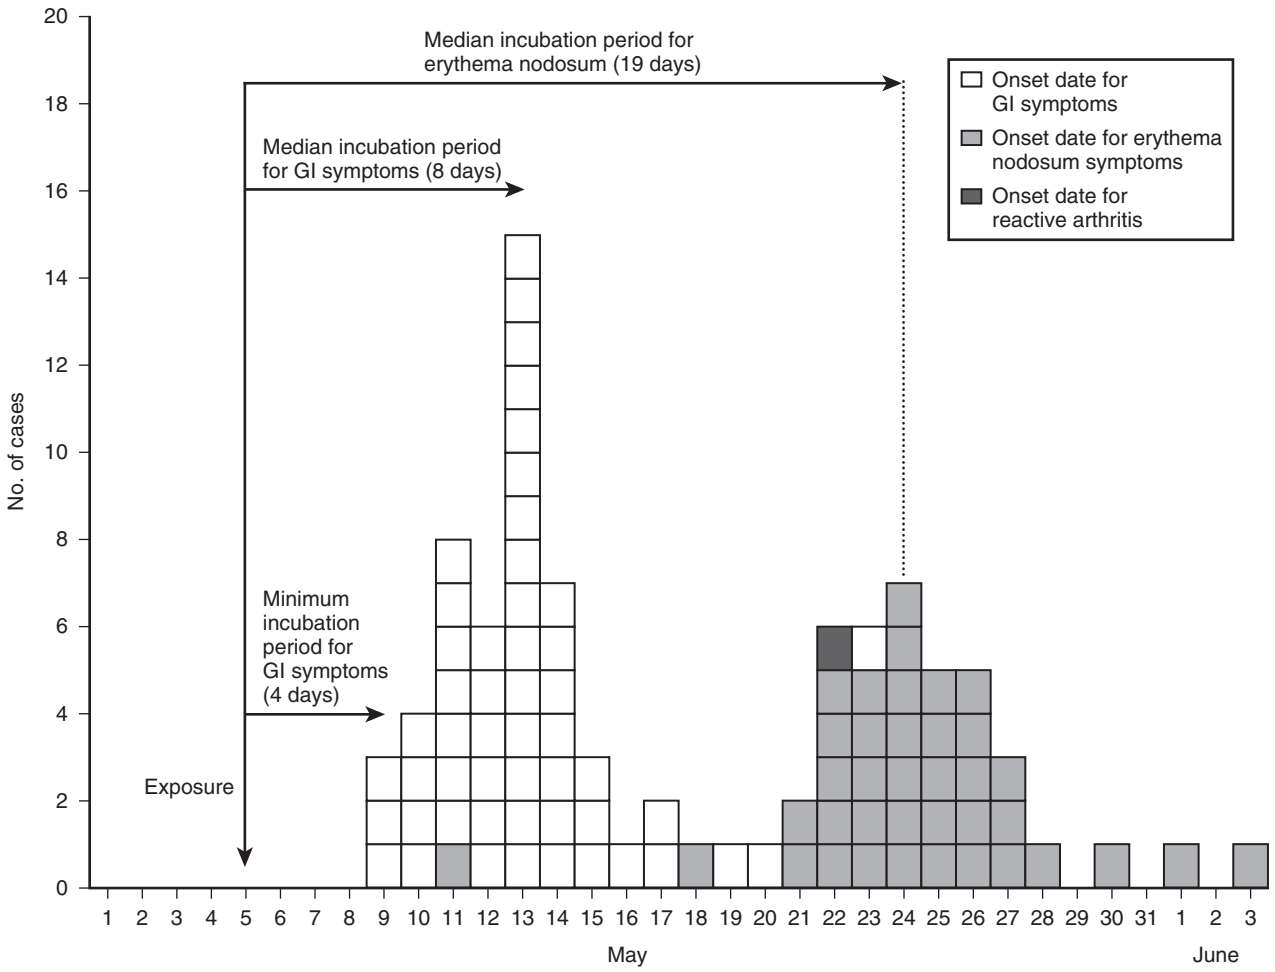

FIGURE 113-2 ■ Distribution of incubation periods for *Yersinia pseudotuberculosis* infection to onset of gastrointestinal (GI) symptoms and erythema nodosum after point source exposure to contaminated carrots. Of 72 case patients with a known date of onset, 51 had GI symptoms and 38 had erythema nodosum only; 28 had GI symptoms and erythema nodosum and appear twice in the graph. (From Jalava K, Hakkinen M, Valkonen M, et al. An outbreak of gastrointestinal illness and erythema nodosum from grated carrots contaminated with *Yersinia pseudotuberculosis*. *J Infect Dis* 2006;**194**:1209-1216.)

hyperplasia of Peyer's patches occurs with scattered microabscess formation.

Ulcers occur primarily over the sites of lymphoid tissue within the mucosa, which accounts for their more longitudinal appearance in the small intestine and an oval or punctate appearance in the stomach and colon. Ulcerations are characterized by necrosis of the epithelial layer. In the colon, the necrosis also may extend through the superficial third of the crypts. Large colonic ulcerations covered by pseudo-membranes or mucoid debris are seen occasionally. Ulcerations may progress to perforation, with subsequent development of peritonitis or gastrointestinal hemorrhage in severe cases.[30,69,219,220]

The inflammatory response in the mucosa consists mainly of neutrophils and mononuclear cells. Lymphocytes and plasma cells also may be seen. Giant cells are not seen, although a granulomatous appearance can be imparted by the presence of plump epithelioid histiocytes. Numerous colonies of gram-negative bacteria often can be seen beneath the mucosal ulcerations and within the microabscesses that occur in the lymphoid tissues.[69,219,220]

The appendix usually appears normal on gross inspection, but small focal ulcerations frequently are present.[7] Large areas of necrosis are found occasionally, and acute, suppurative appendicitis has been reported.[30,104,141] Periappendicular inflammation may result from a true appendicitis or an adjacent terminal ileitis.[219]

Mesenteric adenitis, the hallmark of infection caused by *Y. pseudotuberculosis*, also is a common feature of enterocolitis caused by *Y. enterocolitica*. The lymph nodes usually show numerous large pyroninophilic cells and mitotic figures in the cortical area and marginal sinuses. Small collections of leukocytes in the germinal centers are seen in some cases and suggest formation of microabscesses. In severe cases, extensive areas of necrosis circumscribed by a neutrophilic infiltrate may be seen. The sinusoids can become filled with neutrophils and mononuclear cells. The germinal centers often appear reactive.

The histopathologic appearance of the mesenteric adenitis of infection caused by *Y. enterocolitica* can resemble the adenitides caused by cat scratch disease *(Bartonella henselae)*, toxoplasmosis, infectious mononucleosis, and *Y. pseudotuberculosis*.[7,219,231] The necrotizing epithelioid

granulomata that may be present in mesenteric adenitis caused by *Y. pseudotuberculosis* have not been described in infection caused by *Y. enterocolitica*. A more recent study of six cases suggests that biotype 1B strains may be more likely to cause suppurative inflammation, whereas biotype 2 through 5 strains may be more likely to cause granulomatous infection.[124]

Yersinia pseudotuberculosis

Numerous reports collectively have described the pathology of infection caused by *Y. pseudotuberculosis*.* Grossly enlarged, soft, and inflamed mesenteric lymph nodes are the predominant finding on laparotomy. They frequently are located at the ileocecal angle. Punctate hemorrhages and small, yellow microabscesses may be present on the surfaces of the nodes at the height of infection. The appendix usually appears normal, but the terminal ileum and cecum occasionally appear inflamed. A necrotic purulent mass sometimes is seen in the mesentery.

Histopathologic findings in the mesenteric lymph nodes include enlarged follicles and small abscesses; hyperplasia of reticulum cells; necrosis of the nodes with infiltrates of neutrophilic leukocytes and plasma cells; and, in some instances, punctate hemorrhages. Scattered clusters of neutrophils may be seen within the sinusoids and germinal centers without formation of abscess or necrosis. Atypical mononuclear cells, some of which may be mitotic, may be present in the sinusoids. When necrosis is absent, large numbers of eosinophilic leukocytes occasionally are seen surrounding reticulogranulocytic infiltrates in the nodes. Giant cells can occur and may cause the histologic picture to be confused with that of tuberculosis.

The mesenteric adenitis produced by *Y. pseudotuberculosis* seems to progress through histopathologic stages akin to those of other pyogenic infections that can lead to formation of abscesses.[53,77] Reticulogranulocytic infiltration is followed by formation of an abscess, with subsequent organization and clearing of the abscess. The inflammatory process of *Y. pseudotuberculosis* seems to remain confined to the lymph nodes without rupture through the nodal capsule.

Focal mucosal ulcerations may be seen in the ileum, and are more likely to be found at the site of Peyer's patches. Aggregates of neutrophilic leukocytes similar to those in mesenteric nodes may be seen in germinal centers within mucosal lymphoid tissue. Fibrinoid material may be a prominent feature at these sites. Small areas of necrosis surrounded by reticulum cells and leukocytes also may be present in the submucosal follicles.[62,114,116,227] Ulcerated lymphoid follicles in the intestinal wall are connected to the regional lymph nodes by a lymphangitis. This anatomic situation is analogous to the primary complex of tuberculosis.

Despite a clinical picture of acute appendicitis as the presenting feature of infection by *Y. pseudotuberculosis*, the appendix typically is grossly and microscopically normal. Inflammatory changes, when present, usually are in the form of a periappendicitis. Phlegmonous appendicitis can result from infection caused by *Y. pseudotuberculosis*, but is rare.[53,91]

*References 53, 60, 62, 94, 114, 136, 142, 143, 147, 172, 227.

PATHOGENESIS

The pathogenesis of infection by the two enteropathogenic *Yersinia* spp. has been studied extensively. After ingestion and successful transit to the small intestine have occurred, these *Yersinia* spp. are able to penetrate into the lamina propria primarily by passing through the cytoplasm of M cells that reside on the mucosal surface of Peyer's patches. The bacteria are internalized in membrane-bound vacuoles in which they survive but do not replicate. After reaching the lamina propria, the microbes multiply as extracellular microcolonies in lymph follicles and Peyer's patches, where they may reach densities of 10^9 CFU/g of tissue.[56]

Neutrophils and macrophages infiltrate these sites in response to the infection, ultimately creating microabscesses, but *Y. enterocolitica* is able to resist phagocytosis and intracellular killing by neutrophils and macrophages. *Yersinia* spp. also inhibit production of tumor necrosis factor (TNF)-α and interferon (IFN)-γ and induce apoptosis in host macrophages. The microbes disseminate to the mesenteric lymph nodes, apparently through lymphatic vessels. Infection usually is contained at this point, although abscesses often develop within the nodes. Systemic spread occurs occasionally, more commonly with infection by serotype O:8 strains.

Control of infection caused by *Y. enterocolitica* is the result of T-cell responses that lead to restriction of bacterial growth in infected organs through stimulation of production of *Yersinia*-specific antibody by B cells and cytokine-mediated activation of macrophages. These responses ultimately overcome the antiphagocyte strategies of *Yersinia*. Production of TNF-α and IFN-γ seems to be an essential part of the host response to *Yersinia* infections. *Yersinia* microbes generally do not survive within granulocytes after they have been successfully phagocytosed.[46,48,49,161]

Only a few of the many serotypes of *Yersinia* spp. are capable of infecting humans. Numerous virulence factors have been identified among these "pathogenic" strains (Table 113-2). Most of them are encoded on the *Yersinia* virulence plasmid pYV. At least eight chromosomal loci that encode novel *Yersinia* virulence factors have been found by tagged mutagenesis studies.[67] Much of this knowledge has been gained through mouse and rabbit models of human infection and observations of interactions of *Yersinia* organisms with in vitro cell culture models.[29,46,90,137,168]

The distinctions in pathogenesis between the two enteropathogenic *Yersinia* spp. and *Y. pestis* seem to be caused partly by the presence in *Y. pestis* of (1) two additional plasmids that encode a plasmin activator and a mouse exotoxin and (2) a hemin storage locus on its chromosome. These additional factors may enable *Y. pestis* to survive in and transmit between fleas and rodents. Such transmission does not occur with the enteropathogenic *Yersinia* spp.[180]

TABLE 113-2 **Known and Putative *Yersinia* Virulence Factors***

Stage of Pathogenesis	Determinant	Genomic Origin†	Function	Conditions of Expression
Gastric transit	Urease	Chromosome	Aids survival of gastric acidity.	
Mucosal invasion	Invasin (inv)	Chromosome	Attachment, invasion via β_1 integrins; broad host/cell range.	28°C
	Attachment invasion locus (AiL)	Chromosome	Attachment, lesser invasion factor; more host-specific than invasin; serum resistance.	37°C
	Yersinia adhesin A (YadA)	Plasmid	Attachment, invasion; reduces opsonization by C3b by binding complement factor H; ? role in resistance to antibacterial polypeptides (e.g., bactericidal permeability-increasing protein).	37°C and *any* calcium concentration
Disruption of phagocyte function	Effector proteins (act on host cells)	Plasmid		37°C and low calcium concentration
	YopH		Tyrosine phosphorylase that prevents phagocytosis by macrophages by preventing assembly of focal adhesion structures of phagocytes.	
	YopE		Phagocytosis resistance via induction of host cell actin filament rearrangements.	
	YopJ/P		Cysteine protease/acetyltransferase that inhibits mitogen-activated protein kinase and nuclear factor κB signaling via interruption of posttranslational covalent additions of ubiquitin-like molecules to these enzymes. This prevents production of cytokines (tumor necrosis factor-α), inhibits the host immune response, and triggers apoptosis of macrophages. Inhibits kinase phosphorylation via an acetyltransferase function.	
	YpkA/YopO		Serine kinase, causes rounding up of cells, specific target unknown.	
	YopT		Disruption of actin filaments.	
	YopM		Role unclear. Inhibits thrombin-induced platelet activation in vitro but is delivered intracellularly during infection. Leads to depletion of natural killer cells and alters expression of IL-15 and IL-15 receptors.	
	Membrane attachment, pore insertion into host cell	Plasmid		37°C and low calcium concentration
	YopB and YopD		Pore formation in host cell membrane to allow translocation of effector proteins into the host cell. Suppression of IL-8 secretion by epithelial cells	
	YopQ (YopK)		Controls translocation via modulating the size of the YopB, YopD pore in the host cell membrane	
	YopN		Involved in control of translocation, perhaps stabilizing contact between the bacterium and host cell membranes	

TABLE 113-2 **Known and Putative Yersinia Virulence Factors*** (Continued)

Stage of Pathogenesis	Determinant	Genomic Origin†	Function	Conditions of Expression
	LcrV[e]		Assists extrusion of YopB and YopD to the host cell membrane. Homologue of the *Y. pestis* V antigen. Antibodies against V antigen seem to be protective at the serotype level.	
	Yop secretion apparatus (Ysc) (28 proteins in total; part of microbe)	Plasmid		37°C and low calcium concentration
	YscD, YscR, YscU, and LcrD/YscV		Form a complex that spans the inner bacterial membrane (gated pore/channel).	
	YscC secretin		Forms a pore in the outer bacterial membrane that may connect with the inner membrane pore.	
	YscN		ATPase that energizes Yop transfer across the membranes.	
	LcrQ (in *Y. pseudotuberculosis*), YscM1 and YscM2 (in *Y. enterocolitica*)		Negative *yop* gene regulators that, when secreted, decrease in concentration in the bacterium, allowing *yop* expression.	
	Cytosolic chaperones (Syc) (6 proteins in total; within microbe)	Plasmid	Secretion/translocation pilots or antidegradation roles for effector proteins.	37°C and low calcium concentration
Colonization of Peyer's patches and lymph nodes	*Yersinia* phospholipase A	Plasmid	Serum resistance, inhibition of phagocytosis.	37°C and low calcium concentration
Iron metabolism	Yersiniabactin	Chromosome (high pathogenicity island)	Siderophore.	37°C, iron starvation
Diarrhea	*Yersinia* heat-stable enterotoxin (Yst)	Chromosome	Fluid secretion in intestine. Precise role in pathogenesis of disease in humans is unclear, but found in clinical isolates from children with diarrhea.	28°C (in vitro)
Systemic invasion	O antigen	Chromosome	Component of lipopolysaccharide. Complement/serum resistance.	

Data from references 26, 47, 48, 72, 76, 111, 120, 128, 150, 151, 161, 180, 190, 196, 197, 235, 236.
*The complete pathogenesis/virulence roles of several gene products encoded on the *Yersinia* virulence plasmid pVY and chromosomal sites have yet to be determined.
†Plasmid refers to the *Yersinia* virulence plasmid pYV.
IL, Interleukin; *Lcr,* low calcium response; *Yop, Yersinia* outer membrane protein (although not all such designated proteins reside in the outer membrane).

Bacterial Determinants of Mucosal Invasion

Two outer-membrane proteins encoded by chromosomal genes permit entry into various mammalian cell types in vitro and are likely to be responsible for the ability of *Yersinia* to invade into and through the intestinal mucosal epithelium. They have been named *invasin* and the *attachment invasin locus protein* (Ail). All isolates of *Y. enterocolitica* that are virulent in humans contain DNA sequences that encode for invasin and Ail. Nonpathogenic strains do not contain the genetic code for Ail but most contain invasin genes that cannot be expressed because of chromosomal rearrangements. These proteins apparently are unique to the genus *Yersinia*.[100,145,165]

Invasin attaches to receptors in the β_1 integrin family and induces an actin-mediated endocytosis of the microbe. It binds to β_1-chain integrin receptors with approximately 100-fold higher affinity than do natural ligands, such as fibronectin. Such high-affinity binding triggers endocytosis-like internalization that involves clathrin.[49] Invasin is expressed maximally at ambient temperatures when the organism is in stationary phase. *Y. enterocolitica* microbes living in the environment probably exist in a stationary phase–like state and may be primed maximally for invasion of the host after ingestion. Invasin expression also can remain elevated at 37°C (98.6°F) when the pH is 5.5, and such conditions are encountered during passage through the intestinal tract. Ail is expressed maximally at 37°C, functions as an adhesin and an invasion

factor, and plays a role in the resistance of *Y. enterocolitica* to the bactericidal activity of human serum.[100,101,165]

High levels of β_1-chain integrin receptors are found on the luminal surface of M cells, which are antigen-sampling epithelial cells found in highest numbers overlying Peyer's patches in the intestinal tract.[83] Flagellum-dependent motility seems to be required for invasin-mediated invasion of cells by *Y. enterocolitica*.[233]

The following determinants are primarily relevant to *Y. enterocolitica*, although *Y. pseudotuberculosis* shares many of these features.

Yersinia Adhesin A

Yersinia adhesin A (YadA) is a multifunctional virulence factor of *Y. enterocolitica*. YadA is approximately 50 kDa and probably forms tetrameric fibrillae on the microbial surface. Its gene resides on the pYV plasmid and is transcribed at 37°C independently of the calcium concentration. YadA binds to extracellular matrix proteins, such as collagen, and mediates adhesion to cells. It may play a role in translocation of Yop effector proteins into eukaryotic phagocytic cells. YadA also inhibits the terminal complement attack complex, reduces opsonization by C3b through binding of complement factor H, and contributes to the ability of *Y. enterocolitica* to resist killing by antimicrobial polypeptides of human granulocytes. YadA knockout mutants are far less virulent in mice than is the parent wild-type strain.[48,89,224]

Virulence Plasmid and Type III Secretion System

Pathogenic strains of *Y. enterocolitica* harbor a plasmid that consists of approximately 70 kb (denoted pYV) and encodes the low calcium response system of *Yersinia* spp., which involves a complex response to environmental conditions of 37°C and calcium concentrations of less than 2.5 mM, both of which describe the intracellular compartment of mammalian cells.[48,197] Plasmid-encoded factors are required for survival and extracellular multiplication after reaching Peyer's patches. Plasmid-cured derivatives are ingested rapidly and killed by neutrophils in Peyer's patches, whereas wild-type strains are able to proliferate and spread through the lamina propria to adjacent villi. Plasmid-encoded factors are not required for *Y. enterocolitica* to penetrate the intestinal mucosa.[89]

In DNA cross-hybridization studies, the pYVs of *Y. enterocolitica* serogroups O:9, O:3, and O:5 show 90 percent nucleotide identity with one another, 75 percent identity with the pYV of serogroup O:8, and 55 percent identity with the pYV of *Y. pestis* and *Y. pseudotuberculosis*. Despite the nucleotide divergence among the pYVs of the three *Yersinia* spp., the overall structures and most of the genes are highly similar among them. The *Yersinia* low calcium response plasmids are nonconjugative.[48,197]

The *Y. enterocolitica* pYV contains approximately 70 genes, of which around 53 have protein products with known or putative functions (many of these are listed among the virulence factors in Table 113-2). pYV encodes *Yersinia* adhesin A and a system of six effector proteins that are delivered into host cells (primarily phagocytic granulocytes) through a complex mechanism of regulatory proteins, secretion chaperones, and proteins that act as secretion channels or pores in the bacterial and host cell membranes. This system, called a type III secretion system, denotes secretion of the bacterial proteins only in response to contact with a mammalian cell. The effector proteins and several others involving pore formation are designated Yops (*Yersinia* outer-membrane proteins), although we now know that most of them do not reside in the outer membrane. Similar type III secretion systems are found in *Salmonella* and *Shigella* spp.[48,197]

The secretion system is composed partially of syringe-like organelles—called *Ysc injectisomes*—that develop when *Yersinia* organisms are incubated at mammalian body temperatures. These injectisomes are protein pumps that span the peptidoglycan layer and the two bacterial cell membranes, topped by a needle-like structure protruding outside the bacterium. Twenty-seven proteins are involved in the structure; 10 of them are located internally and appear to be similar to the basal body of a flagellum. The structure also includes an ATPase that functions as a proton pump. A homomultimeric ring-shaped structure extends through the outer membrane, with a central pore diameter of about 50 Å.[34]

As the injectisomes assemble, stocks of intracellular Yops are synthesized. Active transcription of *Yop* genes is limited to bacteria in close contact with eukaryotic cells. The secretion channel of the injectisome remains closed, with negative feedback mechanisms to prevent overproduction of Yops. On close contact with a phagocyte, the injectisome channels open, and secretion of effector Yops into the target cell begins.[34] This is accomplished through insertion of YopB and YopD into the host cell membrane, where these form a multimeric complex that serves as a pore for effector injection.[150]

After secretion into a phagocytic cell occurs, YopH, YopE, YopT, and YopO/YpkA disrupt its cytoskeletal dynamics, blocking phagocytosis (see Table 113-2). YopT is a cysteine protease that cleaves and inactivates Rho proteins, which are small membrane-associated GTPases that control the host cell actin cytoskeleton.[190] Other Yops inhibit production of TNF-α, IL-8, and other inflammatory chemokines and induce apoptosis of macrophages.[34]

A similar type III secretion system is present in *Y. pseudotuberculosis*, which is considered to be primarily an extracellular pathogen.[236] *Y. pseudotuberculosis* can survive within macrophages, and mouse studies suggest a small minority of invading microbes may reside intracellularly in multiple tissue sites. This system is able to transport Yops from phagosomes in macrophages into the cytosol and to inject Yops into mouse dendritic cells. YopJ inhibits dendritic cell–mediated T-cell responses via induction of apoptosis and reduction of surface molecule expression.[210]

Summary *of Yersinia* Pathogenesis

Pathogenic strains of *Y. enterocolitica* require calcium concentrations equivalent to those of serum and extracellular fluids in humans for growth at body temperature. Plasmid proteins are synthesized maximally, however, at 37°C

under conditions of low calcium concentrations, such as those found intracellularly. These regulatory effects of environmental calcium concentrations permit free growth of *Yersinia* organisms during extracellular life and production of factors that inhibit phagocytosis by macrophages and neutrophils when *Yersinia* organisms pass through the intracellular compartment during mucosal invasion or come into contact with these granulocytes.[46,48,89]

A model of how pathogenic *Yersinia* organisms living in cold (≤28° C [≤82.4° F) environmental reservoirs are able to establish infection in the mammalian host can be described at the molecular level (see Table 113-2). *Yersinia* microbes living in the environment express invasin, which renders them ready to attach and invade the intestinal mucosal M cells after ingestion. Expression of invasin continues at body temperature during gastric passage to the intestines. Survival of gastric acidity is assisted by a urease-producing system.

During intracellular passage through M cells in the small intestine, *pYV* genes are likely to be activated (conditions of low calcium, 37° C). YadA can be produced at body temperature and may assist in mucosal invasion. Transcytosis from the intestinal lumen to the lamina propria seems to occur by a clathrin-mediated process that probably is a normal function of the host cell, after internalization is triggered. Ail also is synthesized after ingestion occurs and probably promotes attachment to migrating cells in the lamina propria that may facilitate extracellular spread of the microbes to regional lymph nodes and perhaps the liver and spleen.

To survive this journey, *Yersinia* organisms must evade phagocytosis by macrophages and neutrophils. YadA can inhibit complement opsonization, reducing the likelihood that phagocytosis will occur. When contact between the microbe and a host granulocyte occurs, the previously activated type III secretion system (described earlier) encoded by the pYV plasmid comes into play. A contiguous pore is inserted into the granulocyte cell membrane (involving YopB, YopD, YopQ, YopN, and LcrV). Effector proteins (YopE, YopH, YopJ/P, YopO/A, YopM, and YopT) then are translocated into the granulocyte cytoplasm, disrupting its abilities to ingest the bacterium and produce cytokines and triggering apoptotic cell death (see Table 113-2). Although this system of virulence factors is robust enough to facilitate short-lived infection that often causes mild to moderate clinical symptoms, the microbes that do not succumb to the innate immune response ultimately are contained and then eliminated by the adaptive host response.

Y. pseudotuberculosis, which does not express Ail or invasin, is able to penetrate the intestinal epithelial barrier through a cascade of steps initiated via binding to Toll-like receptor 2 on monocytes. This involves caspase 1 and IL-1β production that ultimately leads to myosin light chain kinase activation in intestinal epithelial cells that disrupts tight junctions between them.[106]

Iron Metabolism and Virulence

Iron is an essential growth factor for most bacteria, many of which release siderophores (high-affinity chelators) that bind ferric iron and then are taken up again through receptors by the microbe. *Y. enterocolitica* serotype O:8 and other biotype 1B strains synthesize a chromosomally encoded siderophore, designated *yersiniabactin*, which sits on the outer membrane of the bacterium. The presence of this siderophore decreases the concentration of environmental iron required for optimal growth and probably accounts for the increased virulence observed for serotype O:8 strains.[50,89] The gene encoding yersiniabactin and the genes required for its biosynthesis, transport, and regulation compose the core of what is termed a *high-pathogenicity island* because of the high lethality for mice that its presence confers.[171]

Serotypes O:8, O:4, O:13, O:18, O:20, and O:21 (all biotype 1B and historically considered "American" strains) are highly lethal to mice after intraperitoneal injection and are able to evoke a keratoconjunctivitis after inoculation into the conjunctival sac of guinea pigs (the positive Sereny test result). Oral infection in mice predominantly produces the features of mesenteric adenitis and systemic infection, rather than simple gastroenteritis, which is characteristic of human infection by American strains. The "European" serotypes, O:3, O:9, and O:5,27, yield a negative Sereny test result and cause mild diarrhea but not death in mice. The European serotypes of *Y. enterocolitica* do not produce yersiniabactin, but are able to use siderophores synthesized by other organisms.[46,89,145]

Deferoxamine, a *Streptomyces*-derived siderophore used clinically to treat iron overload states, can be used by *Y. enterocolitica* strains as a source of iron. The increased availability of ferric iron that exists in iron overload states—for example, hemochromatosis and diseases such as thalassemia, which require frequent red blood cell transfusions—also facilitates survival and growth of *Y. enterocolitica*. Iron overloading and deferoxamine are independent risk factors for development of systemic disease after intestinal infection with *Y. enterocolitica*.[50]

Enterotoxin Production

All enteropathogenic strains of *Y. enterocolitica* produce a heat-stable enterotoxin that closely resembles the heat-stable toxin of *E. coli*. Both enterotoxins induce increases in levels of cyclic guanosine monophosphate levels in intestinal epithelial cells. The *Y. enterocolitica* enterotoxin is not plasmid-encoded, and its presence does not correlate with the expression of other virulence phenotypes.[68] Because the enterotoxin is not produced in vitro at temperatures exceeding 30° C (86° F), production in the gastrointestinal tract and a causative role in diarrhea were thought to be unlikely.[50] Observations in the young rabbit oral infection model have shown, however, that enterotoxin-negative mutants did not induce diarrhea and the wild-type strain did. Clinical biotype 1A isolates from children with diarrhea in India produce *Y. enterocolitica* stable toxin-b. These findings suggest that *Yersinia* enterotoxins may play a role in causing the diarrhea frequently associated with *Y. enterocolitica* infection in children.[89,164,196]

Gastric Acidity as a Protective Host Factor

Although *Y. enterocolitica* is able to grow under conditions at pH 5.0 to 9.0, optimal growth occurs at pH 7.0 to 8.0. Gastric acidity may play a protective role against some *Yersinia* inocula, although pathogenic *Yersinia* organisms produce a urease enzyme that facilitates survival. Therapeutic agents or clinical conditions that result in reduced gastric acidity may predispose patients to development of infection. *Y. enterocolitica* bacteremia has been reported after gastrectomy.[50,120]

CLINICAL MANIFESTATIONS

Clinical disease caused by *Y. enterocolitica* occurs far more frequently than that caused by *Y. pseudotuberculosis*.[61,129,130] Historically, diarrheal illness has been considered the hallmark of *Y. enterocolitica* and the pseudo-appendicular syndrome of mesenteric adenitis indicative of *Y. pseudotuberculosis*. Each species can cause enterocolitis and mesenteric adenitis, however. Various other clinical infections and postinfection syndromes also are caused by these microbes. In a series of patients presenting with acute abdominal pain suggestive of appendicitis, the incidence of serologic evidence of *Yersinia* infection has ranged from 7 to 31 percent.[16]

Yersinia enterocolitica

The clinical features of the disease caused by *Y. enterocolitica*, primarily an acute enteritis, have been described by many investigators.* The clinical manifestations depend partly on the age and physiologic condition of the host.[50,141,172] Enterocolitis is the most common presentation and occurs most often in young children. The pseudo-appendicular syndrome, which results primarily from mesenteric adenitis and mimics acute appendicitis, occurs more commonly in older children and young adults.[20,50,92,104,158,179] Asymptomatic infection can occur, but the relative frequency in contrast to symptomatic disease is unknown. The predominant clinical features of *Y. enterocolitica* infection in children are summarized in Table 113-3. Disease manifestations may be strain-related in some cases. The so-called pathogenic strains of biotype 1B are more likely to cause fever, whereas those of so-called nonpathogenic strains of biotype 1A may cause more vomiting.[97]

Enterocolitis

Y. enterocolitica enterocolitis is characterized by diarrhea and abdominal pain. The diarrhea usually persists for 7 to 14 days.[127,141,219] A range of 1 to 46 days of diarrhea has been reported.[109] Ten percent of cases may persist for 30 days or more,[141] and chronic diarrhea persisting for several months has been described.[54]

During the first week of symptoms, patients commonly have 3 to 10 stools per day, with a gradual decrease in frequency thereafter. Stools typically are greenish, exhibit variable consistency (usually watery or mucoid), and are not remarkably malodorous. Gross blood is noted in approximately 25 to 50 percent of patients. Vomiting occurs in 40 percent of cases. Nausea is a common symptom. The abdominal pain can be colicky, diffuse, or localized to the right lower quadrant or epigastrium. Fever occurs commonly and usually is of low grade, but may exceed 40°C (104°F); it usually resolves within 1 week.[1,138]

Most cases are self-limited, but some children require hospitalization. Among 60 children hospitalized in Michigan between 1990 and 1997, the mean number of hospital days required was 4 (range, 1 to 17 days).[1]

Fecal leukocytes are present commonly but not universally. The peripheral white blood cell count may range from 5600/mm^3 to more than 30,000/mm^3. Most counts are greater than 15,000/mm^3. Band forms often exceed 15 percent of the total. Infants frequently exhibit an immature-to-total neutrophil ratio greater than 0.5.[1,127,138] An absolute monocytosis may be seen in two thirds of

*References 18, 40, 50, 54, 81, 119, 126, 127, 137, 138, 141, 173, 179, 215, 232.

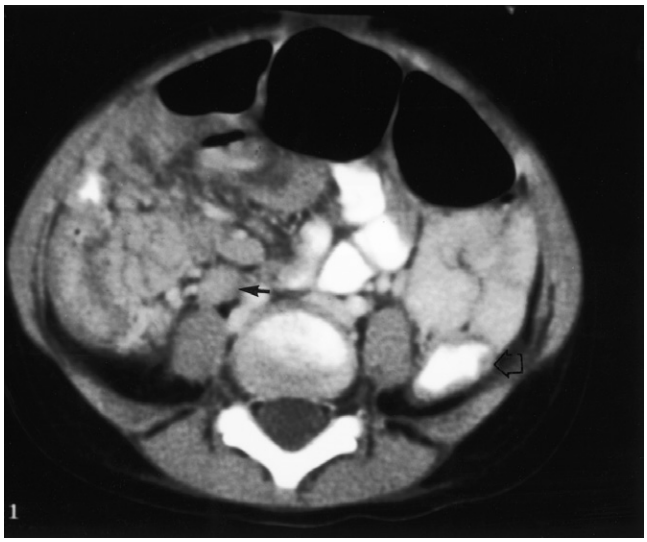

FIGURE 113-3 ■ Mesenteric lymphadenopathy *(solid arrow)* and thickened bowel wall *(open arrow)* seen on computed tomography scan of a toddler with a 1-week history of severe abdominal pain, fever, vomiting, and nonbloody diarrhea. Stool culture on cefsulodin-irgasan-novobiocin agar yielded growth of *Yersinia enterocolitica,* serotype O:8. (From Tuohy AM, O'Gorman M, Byington C, et al. *Yersinia enterocolitis* mimicking Crohn's disease in a toddler. *Pediatrics* 1999;**104**:e36.)

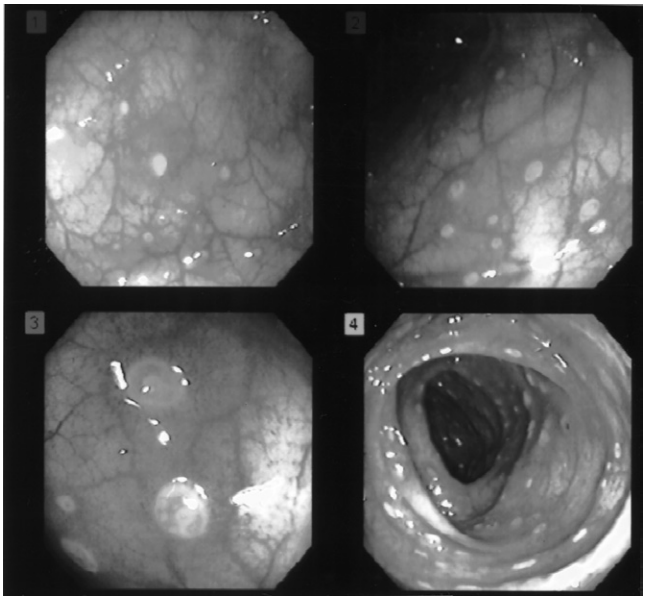

FIGURE 113-4 ■ Multiple mucosal aphthoid ulcerations, 2 to 3 mm in size, as seen during colonoscopy in the child described in Figure 113-3. (From Tuohy AM, O'Gorman M, Byington C, et al. *Yersinia enterocolitis* mimicking Crohn's disease in a toddler. *Pediatrics* 1999;**104**:e36.)

patients.[122] Culture-negative cerebrospinal fluid pleocytosis can occur.[1]

Radiologic examination by upper gastrointestinal barium studies in 24 adult patients with severe diarrhea caused by *Y. enterocolitica* showed abnormalities of the terminal ileum in 21 cases.[220] Diffuse thickening of the mucosal folds was seen in 16 cases, and nodular filling defects were seen in 11. The radiographic appearance suggested the presence of one or more ulcerations of the terminal ileum in 11 patients. Dilation of the terminal ileum was noted in 12 patients, and extrinsic compression, presumably from enlarged lymph nodes, was present in 4. In some instances, the findings suggested the terminal ileitis of Crohn disease. Follow-up studies performed 2 months after acute illness showed decreased but persistent thickening of mucosal folds in eight patients. Barium enema studies were done in 15 patients and showed no striking abnormalities other than mucosal ulcerations, which were seen best on air-contrast studies.[219]

Mesenteric lymphadenopathy can be seen on computed tomography scans (Fig. 113-3).[218] Among 13 adults who had colonoscopy or sigmoidoscopy for severe diarrhea caused by *Y. enterocolitica*, abnormalities were seen in 8; the mucosa appeared diffusely swollen, erythematous, and friable in 6 individuals, and 2 had only small, 1- to 2-mm aphthoid ulcerations. Serial procedures showed macroscopic and microscopic healing of ulcers within 4 to 5 weeks.[220] Aphthoid ulcerations may be seen throughout the colon (Fig. 113-4).[218]

Pseudoappendicitis-Mesenteric Adenitis

The syndrome of pseudoappendicitis, characterized in most cases by a normal appendix and an intense suppurative mesenteric adenitis, has attracted considerable attention since it was reported first in 1953.[142,143] The first recognized cases were caused by *Y. pseudotuberculosis*, but most cases reported in recent years have been caused by *Y. enterocolitica*.[31,103,126]

Fever, abdominal pain, right lower quadrant tenderness, and leukocytosis are the primary features of *Y. enterocolitica*–induced pseudo-appendicular syndrome.[50,104] Some patients also have features of enterocolitis (i.e., nausea, vomiting, and diarrhea). The clinical presentation often is highly suggestive of acute appendicitis, such that laparotomy is required. Among a series of 581 patients in Scandinavia who underwent laparotomy for suspected appendicitis, 3.8 percent of cultures of stool or operative specimens yielded *Y. enterocolitica*.[158] Another 284 patients with similar symptoms were observed, and 5.6 percent of stool cultures from these cases yielded *Y. enterocolitica*. In a similar Scandinavian series of 205 patients who underwent appendectomy, 22 subsequently were diagnosed by serology as having *Y. enterocolitica* infection.[104] The findings on laparotomy usually are mesenteric lymphadenitis, terminal ileitis, and a normal or slightly inflamed appendix.[20,50,104,158]

A study of 40 cases of granulomatous appendicitis found evidence suggesting infection caused by *Y. enterocolitica* in four specimens, *Y. pseudotuberculosis* in four specimens, and both in two specimens by PCR analysis.[125] Two patients in the series subsequently were diagnosed as having Crohn disease, but causation cannot be inferred.

Asymptomatic Infection

In an unknown number of cases, infection by *Y. enterocolitica* is entirely asymptomatic. In a study of the

distribution of antibodies to *Y. enterocolitica* in sera collected for various purposes in Ontario, Canada, from 4209 individuals who had no evidence of infection by this organism, specific antibody was present in 199 (serotype O:3 in 158 and serotype O:9 in 41).[215]

Other Presentations of Acute Infection

Bacteremia can occur[35,41,50,149] and may result in spread of infection to virtually any body site. Such events occur uncommonly and are seen more often in adults than in children. In children, bacteremia occurs more commonly in infants than in older children.[1] The risk for development of bacteremia during gastroenteritis in infants younger than 3 months may be 30 percent.[153] Bacteremias may be transient and asymptomatic or lead to septic shock and death. Septic cases tend to occur among patients with underlying illnesses and are associated with mortality rates of 34 to 50 percent.[50]

Y. enterocolitica may cause focal infections in many extraintestinal sites, even in the absence of detectable bacteremia. Pharyngitis has been reported and occurs primarily in adults. Cervical adenopathy may be associated with *Y. enterocolitica* pharyngitis, and gastrointestinal symptoms may be absent.[50] One adult with pharyngitis died of associated septic shock.[181] Conjunctivitis and panophthalmitis caused by *Y. enterocolitica* have been described. Parinaud oculoglandular syndrome,[42] inguinal adenopathy,[228] and suppurative lymphadenitis[217] have been reported, including a neonate with inguinal adenitis.[159]

Cellulitis, soft tissue abscesses, and wound infections also have been reported. Cellulitis may have associated vesiculobullous lesions. An erysipelas-like rash, maculopapular rash, and urticaria also have been described in association with infection caused by *Y. enterocolitica*.*

Pancreatitis, cholecystitis, diverticulitis, and intestinal perforation have been described.[129,169] Peritonitis also can occur but is extremely rare,[175] especially considering the frequency of mesenteric adenitis. Pneumatosis intestinalis has been reported in an infant.[1] Pneumonia, pleural empyema, lung abscess, hepatic and splenic abscesses, urinary tract infection, and renal abscess also have been reported.[50] Glomerulonephritis that usually is transient has been reported.[51,65] Cases of meningitis, osteomyelitis, septic arthritis, pyomyositis (including psoas muscle abscess), endocarditis, mycotic aneurysm, and intravenous catheter–related infection caused by *Y. enterocolitica* have been described.† Thrombocytopenia[70] and hemolytic anemia[117] have occurred in association with infection caused by *Y. enterocolitica*.

Underlying Conditions That Predispose to Bacteremia

Y. enterocolitica bacteremias that occur in patients beyond early infancy most often occur in patients with chronic illnesses or iron overload states. Thalassemias are such conditions that occur most commonly in children.[40,63,110] Among 144 Italian children with thalassemia who were receiving deferoxamine therapy and frequent blood transfusions, 14 developed infection caused by *Y. enterocolitica* during a 12-month period.[40] Septicemia occurred in 5 of the 14 and was preceded by enterocolitis or mesenteric adenitis in each case. All 14 recovered after receiving 2 weeks of therapy with intravenous trimethoprim-sulfamethoxazole. A similar proportion of children with thalassemias observed in two centers in Canada between 1979 and 1994 also developed invasive disease caused by *Y. enterocolitica*.[6] Bacteremia can be associated temporally with blood transfusions in such patients, suggesting that transfusions may be the source of infection or predispose to development of infection in some cases.[129]

Hemochromatosis, cirrhosis, and other liver diseases may facilitate development of *Y. enterocolitica* bacteremia, also on the basis of excess availability of serum iron. Deferoxamine therapy itself is a risk factor for development of sepsis caused by *Y. enterocolitica* because of the ability of the microbe to extract iron from this compound. Immunosuppressive therapies, diabetes mellitus, and malnutrition also may predispose to development of *Y. enterocolitica* bacteremia.[50]

Postinfectious Syndromes

A reactive arthritis may occur 1 to 14 (usually 4 to 10) days after the cessation of acute illness.* Most such events occur in adults, with a slight female predominance, but 8/74 cases in one series from Sweden were in children aged 11 to 20 years old (5 boys, 3 girls).[230] In a series from the Netherlands, 10 percent of children with yersiniosis, most of whom were 7 years of age or older, developed arthritis.[93] The knees, ankles, and wrists are affected most commonly, and in approximately 50 percent of cases, only one or two joints are involved. Hands, fingers, toes, shoulders, hips, and elbows also may be involved. Pain usually is severe, and the arthritis is additive and usually not migratory. The inflammatory process is self-limited and may persist for 2 months or longer in two thirds of cases, with one third persisting for 4 months or longer.

The erythrocyte sedimentation rate exceeds 60 mm/hr in approximately 50 percent of cases. Joint effusions usually are inflammatory, but cell counts and differentials vary and occasionally mimic septic arthritis. Immune complexes have been found in joint fluid. Nonsteroidal anti-inflammatory drugs and corticosteroids, intra-articular and systemically administered, have been used for symptomatic relief for this process.[178]

Erythema nodosum also occurs as a postinfectious manifestation, more often in adults than in children. It can occur alone or in association with arthritis.[86] Tendinitis, myositis, myocarditis, urethritis, uveitis, and conjunctivitis also can occur in association with arthritis. Many but not all patients who develop these postinfectious reactions are human leukocyte antigen (HLA)-B27 positive.[1] Some patients manifest full Reiter syndrome.[93,118,185,199] Acute glomerulonephritis has been

*References 18, 31, 50, 78, 192, 209, 229.
†References 12, 32, 50, 90, 201, 203.

*References 7, 8, 10, 13, 90, 93, 179, 212, 220, 230.

linked to infection with serotype O:3 strains in one series of adults.[65]

Yersinia antigens, but not intact bacteria, have been found in synovial tissue obtained several weeks to months after onset of reactive arthritis. *Y. enterocolitica* is able to survive within in vitro cultures of human synovial cells for 6 weeks, with resultant deposition of residual antigen aggregates within the cells.[98] Synovial fluid–derived T cells from patients with *Y. enterocolitica*–induced reactive arthritis have been shown to respond to several *Y. enterocolitica* antigens: heat shock protein 60, urease β subunit, ribosomal L2 protein, and a region of the plasmid-encoded tyrosine phosphatase YopH that is highly homologous to the catalytic domain of eukaryotic protein tyrosine phosphatases.[123,144,167]

Epitopes on *Yersinia*-produced proteins likely trigger cross-reactive immunologic recognition of host proteins that leads to chronic inflammation in susceptible individuals.[95] High levels of antibodies that react with 60-kDa recombinant *Yersinia* heat shock protein have been found in HLA-B27–positive individuals with acute anterior uveitis or pars planitis.[34]

Antibodies against *Y. enterocolitica* have been detected in patients with disorders of the thyroid, including Graves disease, thyroid adenoma, and Hashimoto thyroiditis.[193] A Danish twin study found no increased risk for thyroid antibodies after *Y. enterocolitica* infection, however.[84] These observations may reflect autoantibodies that cross react with *Yersinia* epitopes, rather than a causal link between yersiniosis and thyroid disease.[50,176]

Brachial plexus neuropathy and transverse myelitis, each occurring after the resolution of gastrointestinal symptoms caused by *Y. enterocolitica*, have been described in one patient.[204] Various chronic ailments have been described among a group of 160 Scandinavian patients observed for 4 to 14 years after having acute yersiniosis.[186] Ailments included persistent joint complaints, ankylosing spondylitis (in HLA-B27–positive patients), iridocyclitis, chronic hepatitis, chronic abdominal pain, rheumatoid arthritis, chronic nephritis, thyroid disease, and neurologic ailments. Observed deaths among these patients exceeded the expected number. These findings require confirmation before causal links can be considered.

Yersinia pseudotuberculosis

The pseudo-appendicular syndrome that results from mesenteric adenitis is the primary disease produced by *Y. pseudotuberculosis*.* The chief complaint is abdominal pain, either diffuse or localized to the right lower quadrant. Fever (38° to 40° C) (100.4° to 104° F) almost always is present. Tenderness over the McBurney point usually is present. All of these symptoms are highly suggestive of acute appendicitis. Diarrhea may occur but often is absent. Mild leukocytosis occurs, but white blood cell counts usually are less than 20,000/mm^3. The clinical course almost always is benign, with recovery typically beginning approximately the fifth day of illness. On laparotomy, the appendix is normal in most cases but occasionally appears inflamed or suppurative. The mesenteric lymph nodes are enlarged and may appear necrotic.

Efforts have been made to distinguish the pseudoappendicular syndrome caused by *Y. pseudotuberculosis* from that caused by *Y. enterocolitica*.[28,71] *Y. pseudotuberculosis* adenitis is less likely to have associated enterocolitis and may have a shorter febrile course, but no clear distinction can be made on clinical grounds alone.

A fulminant typhoidal or septicemic form of infection caused by *Y. pseudotuberculosis* can occur but seems to affect primarily older adults with debilitating conditions, such as diabetes or liver disease. This syndrome often is fatal.[114,185] Isolated cervical adenitis, liver abscess, and terminal ileitis have been described.[86,227] Subacute and recurrent disease can occur.[136] Erythema nodosum[185] and nonsuppurative arthritis[39] also have been reported in association with infection caused by *Y. pseudotuberculosis*. In an outbreak related to eating contaminated grated carrots in Finland in 2003, erythema nodosum was seen in numerous patients with gastrointestinal illness.[102] Median time from exposure to development of gastrointestinal symptoms was 8 days. Median time from exposure to development of erythema nodosum was 19 days (see Fig. 113-2). One patient developed reactive arthritis in a similar time frame.

Yersinia pseudotuberculosis *and Kawasaki Disease–Like Illness*

In Korea and Japan, *Y. pseudotuberculosis* strains have been responsible for a clinical syndrome that can mimic Kawasaki disease.[39] This manifestation of disease occurs primarily in outbreaks and has been described as scarlet fever–like.[162] A transient (2 to 3 days) erythematous maculopapular rash, strawberry tongue, conjunctivitis, and desquamation can occur, generally in association with gastrointestinal symptoms and fever. Erythema nodosum, lymphadenopathy, uveitis, and coronary aneurysms have occurred in some of these cases, as has acute interstitial nephritis, which can lead to transient renal failure.[3,121,162] Among a series of 33 patients (median age, 5 years) with such presentations, 20 had elevated antibody titers against *Y. pseudotuberculosis*–derived mitogen, which can function as a superantigen.[3] As in Kawasaki disease, Vβ3 T lymphocytes were increased in many of these patients in contrast to healthy control subjects.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of *Yersinia* enterocolitis includes viral and other bacterial causes of acute gastroenteritis. When the symptoms of mesenteric adenitis are predominant and severe, appendicitis and other causes of an acute abdomen must be considered. The acute terminal ileitis caused by *Yersinia* infections also can be similar to the gastrointestinal manifestations of Crohn disease, ulcerative colitis, cat scratch disease, anisakiasis, amebiasis, actinomycosis, typhoid fever, and lymphoma.[69,93,162,219,227] Cases of infection caused by *Y. enterocolitica* with concomitant recovery of *Salmonella* and *Campylobacter* spp.

*References 21, 53, 60, 62, 71, 91, 96, 113, 114, 136, 162, 183, 185, 222, 227.

and rotavirus antigen in stool specimens have been observed.[1]

DIAGNOSIS

The most effective approach to the diagnosis of yersiniosis is isolation of the organism from the stool of patients with enteritis caused by *Y. enterocolitica* or from the infected mesenteric lymph nodes of patients infected by *Y. pseudotuberculosis*. *Y. enterocolitica* occasionally can be recovered from involved mesenteric lymph nodes or the distal ileum.[50] Cultures of feces from individuals with acute suppurative mesenteric adenitis usually fail to grow either organism.

Isolating *Yersinia* organisms from extraintestinal specimens such as lymph nodes and blood is not difficult because they grow on ordinary media (e.g., blood agar) and on several selective and differential media employed for enteric bacteria. Isolating from fecal specimens is more difficult, however, because *Yersinia* multiply more slowly than other enteric bacteria at 37° C (98.6° F) and have no characteristic colony morphology. Selective media have been developed, but many clinical laboratories culture stool specimens for *Yersinia* spp. only on request because of the costs of these media and the relatively low frequency of occurrences of these pathogens in the community.

Yersinia organisms grow well on MacConkey agar but are much smaller than are other enteric bacteria after standard incubation at 37° C. Cefsulodin-irgasan-novobiocin agar plates have been designed specifically for the isolation of *Yersinia* spp. from stool specimens. After being incubated for 48 hours, *Yersinia* colonies appear dark pink with translucent borders and occasionally are surrounded by a zone of precipitated bile. Cefsulodin-irgasan-novobiocin agar inhibits the growth of most other bacteria except for *Citrobacter* spp. (positive citrate reactions of which allow their distinction). If a dedicated medium for *Yersinia* isolation is not used, MacConkey agar can be examined after 24 hours at 35° to 37° C (95° to 98.6° F) for small colorless colonies that become much larger after an additional 24 hours of incubation at room temperature. Most *Y. enterocolitica* strains are lactose-negative.[74] *Yersinia* spp. can be differentiated readily from *Salmonella* spp. because the latter are motile at 37° C, urease-negative, citrate-positive, and lysine-positive. Most *Salmonella* strains also produce gas during fermentation and produce hydrogen sulfide. *Shigella* are urease-negative and lack motility at room temperature.[203]

Yersinia spp. grow faster at 37° C than at room temperature. Growth occurs readily at 22° to 28° C (71.6° to 82.4° F), however, and these lower temperatures are recommended for primary isolation.[74] Because of the ability of *Yersinia* spp. to grow at even colder temperatures, specimens can be inoculated into phosphate-buffered saline, refrigerated at 4° to 6° C (39.2° to 42.8° F), and subcultured periodically (up to 4 weeks) if the routine plates that were inoculated with the specimen remain negative. Such "cold enrichment" greatly enhances the isolation rate of *Yersinia* spp. and may be the most reliable method for isolating these organisms from fecal specimens. Many of the *Yersinia* isolates recovered by cold enrichment, however, represent either *Y. enterocolitica* serotypes, which usually are not associated with human disease, or other *Yersinia* spp., which have roles that remain unclear.

Pathologic or virulent *Yersinia* strains can be distinguished in most instances from nonpathogenic strains by three biochemical tests that are associated with absence of the virulence plasmid. The virulent strains lack pyrazinamidase activity, do not ferment salicin, and do not hydrolyze esculin. On Congo red–magnesium oxalate agar during incubation at 36° C (96.8° F), fresh pathologic isolates (but not those that have been subcultured serially) grow as small red colonies, showing the virulence plasmid-determined properties of Congo red dye uptake and calcium-dependent growth.[59]

Serology

Serology can be performed with microtiter techniques and is most reliable for serotypes O:3 and O:9 of *Y. enterocolitica*. Antibody to the infecting serotype usually is absent at the onset of disease. Peak titers usually are reached 3 to 4 weeks after onset of clinical illness and decrease during the next 3 to 5 months. Low postconvalescent titers may persist for months. Microhemagglutination, complement fixation, and enzyme immunoassays are available in a few commercial laboratories.[27,74,219]

Agglutinin titers of 1 : 128 or higher for *Y. enterocolitica* in previously normal healthy individuals suggest infection. Titers of 1 : 200 or greater were present within 3 weeks of onset of illness in 62/65 Canadian children who had infection with serotype O:3. Fourfold increases in titer rarely were seen. Negative or minimal titers (≤1 : 32) do not rule out yersiniosis in infants or immunosuppressed patients. Serologic responses occur more commonly and are of higher titer among patients with extraintestinal systemic infection. Prozone reactions may occur at dilutions of 1 : 32 or lower. Marked cross agglutination occurs between *Y. enterocolitica* serotype O:9 and *Brucella abortus*, *Morganella morganii*, and *Salmonella*.[27,141] Antibodies to *Y. pseudotuberculosis* often are detectable at the onset of clinical signs of infection and may be highest during the acute phase of illness.[91]

Molecular Techniques

PCR assays have been developed for *Y. enterocolitica* and *Y. pseudotuberculosis* with use of primers that allow assessment of 16S rRNA sequences and of specific plasmid-encoded and chromosome-encoded genes.* PCR techniques have been used to identify *Yersinia* organisms in blood, tissue, stool, water, and food samples.[85,124]

TREATMENT

Most patients with yersiniosis do not require treatment because the disease usually is self-limited. Seriously ill

*References 39, 125, 154, 155, 223, 225.

patients generally have responded to treatment with chloramphenicol, gentamicin, or tetracyclines, but clinical success has not been uniform. Of these agents, tetracyclines have been the traditional agent of choice.[71,219] *Y. enterocolitica* isolates resistant to the tetracyclines have been reported in recent years, however. Two percent of a sample of *Y. enterocolitica* isolates from Canada in 1992 were resistant to tetracycline,[166] and 10 percent of a sample of *Y. enterocolitica* isolates from the Netherlands from 1982 to 1991 were resistant to doxycycline.[206]

More than 99 percent of 1060 isolates of *Y. enterocolitica* collected in Canada in the years 1972 to 1976, 1980, 1985, and 1990 were susceptible in vitro to piperacillin, cefotaxime, aztreonam, gentamicin, tobramycin, amikacin, trimethoprim-sulfamethoxazole, chloramphenicol, and ciprofloxacin. No evidence of decreasing susceptibility to any of these agents was found across the periods sampled. These results were mirrored by a study of 335 isolates obtained in the Netherlands from 1982 to 1991. All of these isolates were susceptible to ceftazidime, cefepime, imipenem, trimethoprim-sulfamethoxazole, ciprofloxacin, and ofloxacin. Aminoglycosides were effective against more than 99 percent, chloramphenicol was effective against 94 percent, and cefuroxime was effective against 90 percent. Seven multidrug-resistant isolates were present among the isolates from Canada, but none was found among the isolates from the Netherlands.[166,206]

Most *Y. enterocolitica* isolates, regardless of serotype, are resistant to ampicillin, ticarcillin, and first-generation cephalosporins. Most of them also are resistant to amoxicillin-clavulanic acid. This is likely due to expression of β-lactamase *BlaA* and/or *BlaB* genes, because most *Y. enterocolitica* strains harbor both.[22] Azithromycin was active in vitro against 50 percent of the 335 isolates in the Netherlands, but almost all isolates were resistant to erythromycin and clarithromycin.[166,206] Antimicrobial resistance of *Y. enterocolitica* strains in Europe does not appear to have increased in recent years.[22]

The decreasing effectiveness of tetracyclines in vitro raises the question of whether these agents should be the first choice for treatment of infection caused by *Y. enterocolitica*. A retrospective review of 43 cases (with patient ages ranging from 3 to 89 years) treated for *Y. enterocolitica* septicemia in France between 1985 and 1991 showed that third-generation cephalosporins were effective in 85 percent of cases in which they were used, although aminoglycosides or fluoroquinolones usually were administered concurrently.[66] Fluoroquinolones alone or in combination with other agents cured all 15 patients. Seven children with bacteremia and diarrhea in Michigan responded well to cefotaxime.[1]

In a double-blind, placebo-controlled trial of trimethoprim-sulfamethoxazole for treatment of children with gastroenteritis caused by *Y. enterocolitica*, the clinical course of illness was not shortened.[163] The children had been ill for a mean of 12 days before treatment was begun, however.

Systemic infections, extraintestinal focal infections, and enterocolitis in compromised hosts should be treated with antibiotics.[50] The in vitro susceptibilities and limited clinical data suggest that children with such infections should be treated with a third-generation cephalosporin, an aminoglycoside, or both. Trimethoprim-sulfamethoxazole also may be used.[40,93] Fluoroquinolones also probably would be effective. Cefotaxime and ceftriaxone were effective in treating bacteremia in a series of 12 children.[2]

Even fewer clinical and in vitro susceptibility data are available for *Y. pseudotuberculosis*. These infections probably can be managed identically to *Y. enterocolitica* infections. A recent analysis of 12 strains in Germany found no resistance to agents tested, including ampicillin.[22] All isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* should be examined for susceptibility to a variety of antibacterial drugs.

VACCINES

There are no vaccines for *Yersinia* species at this time, although work to develop a new and improved vaccine against *Y. pestis* is ongoing. An attenuated *Y. pseudotuberculosis* strain (IP32953) transformed to express the *Y. pestis* F1 capsule conferred 100 percent protection in mice against a high challenge dose of *Y. pestis* after a single oral dose of the vaccine strain.[55]

OTHER *YERSINIA* SPECIES

Eleven other "non-pestis" *Yersinia* spp. (*Y. frederiksenii*, *Y. intermedia*, *Y. kristensenii*, *Y. aldovae*, *Y. bercovieri*, *Y. mollaretii*, *Y. rohdei*, *Y. alecksiciae*, *Y. similiensis*, *Y. massiliensis*, and *Y. ruckeri*) occasionally have been isolated from clinical specimens, but their roles as human pathogens remain unclear.[74,192,194,207] Each except *Y. aldovae* has been isolated from humans worldwide, including individuals with gastrointestinal disorders.[207] These microbes also can be found in fresh-water sources, sewage, dogs, pigs, cattle, wild mammals, birds, reptiles, fish, and some foods, especially milk and meat products.

These organisms are similar biochemically to one another and have been termed atypical *Y. enterocolitica*.[50] None contains the *Yersinia* virulence plasmid pYV.[145] Some contain other large plasmids distinct from pYV, carriage of which may be associated with the ability to cause diarrhea in humans.[164,207] A heat-stable enterotoxin has been found in isolates of *Y. bercovieri*.[208] These *Yersinia* spp. can grow at 4° C (39.2° F) and on cefsulodin-irgasan-novobiocin agar and can multiply in refrigerated foods.

These species occasionally may cause diarrhea and other gastrointestinal symptoms, especially in immunocompromised hosts or individuals with gastric acid suppression.[133] Use of cold enrichment techniques may enhance recovery of these organisms. Their isolation from clinical specimens should not be disregarded or deemed causative of clinical disease without careful epidemiologic considerations.[74] Isolates of these species sometimes can be misidentified as *Y. enterocolitica* by commercial identification systems used in many clinical laboratories. Differences in colony morphology, pyrazinamide reactions (negative for *Y. enterocolitica*), and other biochemical tests can be used to distinguish them from *Y. enterocolitica*.[80,109]

CHAPTER 114

Miscellaneous Enterobacteriaceae

Randall G. Fisher

Three less commonly isolated organisms of the family Enterobacteriaceae are *Edwardsiella tarda*, *Hafnia alvei*, and *Pantoea agglomerans.* Each of these organisms, although uncommon, can cause significant disease in certain clinical circumstances.[65]

EDWARDSIELLA TARDA

BACTERIOLOGY

E. tarda is a non–lactose-fermenting, gram-negative bacillus that is indole positive and produces hydrogen sulfide. It ferments only glucose and maltose. The species name *tarda* reflects its biochemical inactivity. It usually is lysine positive and ornithine decarboxylase positive.[27] The organism resembles *Salmonella* biochemically and

clinically.[41] *Salmonella* usually ferments mannitol, sorbitol, and rhamnose, however. The innate resistance of *Edwardsiella* to colistin also distinguishes it from *Salmonella*.[68] *E. tarda* grows well on usual differential media in the laboratory and produces smooth, glistening, semitranslucent colonies.

EPIDEMIOLOGY

E. tarda is an organism associated with fresh-water and marine life and has been isolated from turtles, fish, pelicans, alligators, seals, and toads.[41] It also is found in snakes and lizards. Case reports of human disease have implicated ornamental fish,[93] pet turtles,[69] snakes,[80] and catfish[7,17,35] and injuries in fresh and brackish water.[86]

Patients with chronic liver disease, chronic ethanol abuse, corticosteroid therapy, and hemoglobinopathy particularly are prone to developing infection with *E. tarda*.[59] Any condition associated with iron overload also is a potential risk factor. Serious infections with *E. tarda* in otherwise well individuals also can occur.[86]

Infection with *E. tarda* is global but occurs more commonly in tropical and subtropical climates, particularly Southeast Asia, Africa, and Latin America.[49] The elderly and the very young seem to be at increased risk for developing severe illness.[11] Asymptomatic carrier states have been documented well,[74] but no true epidemic has been reported, and person-to-person transmission has not been established directly.[24]

PATHOPHYSIOLOGY

Invasiveness of the organism in HeLa and HEp-2 cells,[77] siderophore production, the elaboration of a cell-associated hemolysin,[37] and resistance to complement-mediated lysis may contribute to virulence, although no clear associations have been made.[45] Hemolytic activity requires the presence of two genes, *ethA* and *ethB*. The *ethA* gene codes for the hemolysin, whereas the *ethB* gene codes for an activation/secretion protein, which is necessary for activation of the hemolysin. Transcription of the *ethB* gene is regulated by iron, which may explain the association between iron overload states and severe *E. tarda* infection.[37] Hemolysin activity seems to be necessary for cell entry and cytotoxicity.[89] *E. tarda* produces an iron-cofactored superoxide dismutase that inhibits macrophage-mediated innate immune responses.[15] *E. tarda* has both type III and type VI secretion systems; expression of these gene products is regulated by phosphorus and iron concentrations.[14]

CLINICAL MANIFESTATIONS

Infections with *E. tarda* can be divided broadly into two types: intestinal and extraintestinal. Approximately 80 percent of infections are intestinal.[86] Gastrointestinal infection usually causes self-limited enteritis, with intermittent watery diarrhea and low-grade fever.[40] Nausea and vomiting usually are not seen. Occasionally, enterocolitis or a dysentery-like illness is noted.[61] Because most laboratories do not culture stool specimens specifically for *Edwardsiella*, most cases are unrecognized.

Wound infection is the most common extraintestinal infection. Most of the wounds are caused by fish fins or snakes; wounds sustained in automobile accidents also have been implicated.[42] Cellulitis or abscesses may be produced. Coinfection with other organisms, particularly *Aeromonas hydrophila*, is common.[35,86] One case of necrotizing fasciitis and myonecrosis in an immunocompetent man has been reported. Cultures obtained at surgical débridement yielded a pure growth of *E. tarda*.[86]

Septicemia with *E. tarda* is a rare but serious infection that carries a mortality rate of approximately 45 percent. Most patients with septicemia have underlying conditions, such as liver disease, iron overload, diabetes mellitus, and immunosuppression. Septicemia occasionally follows a mild diarrheal illness.[17] Infants without other risk factors have been reported.[95] Septicemia manifests as high fever, shock, and, often, disseminated intravascular coagulation. Meningitis and multiple brain abscesses also have been reported.[83,90,97] Death sometimes occurs despite administration of appropriate antimicrobial therapy.

Other syndromes associated with *E. tarda* infection include an enteric fever–like illness,[17] multiple or solitary liver abscesses,[50,102] osteomyelitis,[80] septic arthritis,[7] cellulitis,[31] myonecrosis,[86] necrotizing fasciitis,[64] endocarditis,[70] uterine pyomyoma,[100] tubo-ovarian abscess,[78] and peritonitis.[17] A case of puerperal intrauterine infection in a woman without obvious risk factors has been reported; her infant was not affected.[66] In another case, neonatal sepsis resulted from maternal chorioamnionitis.[36] Patients with sickle-cell disorders may be predisposed to bony infection with *E. tarda*, as they are with *Salmonella*.[83,99] Reported cases all are in patients with sickle-cell hemoglobinopathy, rather than homozygous sickle-cell disease. Osteomyelitis has also been reported in X-linked chronic granulomatous disease.[47]

DIAGNOSIS AND TREATMENT

Diagnosis rests on identification of *E. tarda* in culture. The major pitfall is mistaking it for *Salmonella*.

E. tarda is sensitive in vitro to most antibiotics used routinely in the treatment of gram-negative infections, including β-lactams, cephalosporins, aminoglycosides, and fluoroquinolones.[16] It also is sensitive to chloramphenicol, trimethoprim-sulfamethoxazole, and tetracycline.[88] Resistance to polymyxin B, colistin, and, occasionally, penicillin has been shown.[16,17] The organism almost universally elaborates a β-lactamase, but no resistance to β-lactams other than penicillin[16] and oxacillin[88] has been reported.

Gastrointestinal disease usually does not require treatment. Severe disease, such as septicemia or meningitis, probably should be treated with the combination of a β-lactam and an aminoglycoside,[41] even though synergy has not been shown.

HAFNIA ALVEI

BACTERIOLOGY

H. alvei is a facultatively anaerobic, gram-negative bacillus, formerly referred to as *Enterobacter hafnia*.[84] This indole-negative, catalase-positive, and oxidase-negative organism is positive for lysine and ornithine decarboxylases. It is motile at lower temperatures but may be immotile at temperatures of 35° C (95° F) and greater. *H. alvei* ferments mannitol, maltose, and sucrose. It grows well on blood or MacConkey agar as a nonlactose fermenter, producing gray-white, slightly elevated, glistening colonies.[26] For a long time *H. alvei* was thought to be the only species within the genus *Hafnia;* however, in 2010, members of DNA hybridization group 2 were reclassified as *H. paralvei* sp. nov.[38]

EPIDEMIOLOGY

H. alvei has been found in soil, dairy products, sewage, and the feces of humans and animals. Some question exists as to whether it is part of the endogenous microflora of the gut[81] or whether an asymptomatic "carrier" state exists. One study from Japan cultured *H. alvei* from 13 percent of healthy subjects[63]; other epidemiologic surveys have shown the incidence to be less than 2 percent.[82] Long regarded as a nonpathogen, *H. alvei* now has been associated clearly with enteritis and rarely has been isolated in pure culture from other sites, including blood, cerebrospinal fluid, peritoneal fluid, and urine. Infection seems to be opportunistic.

PATHOPHYSIOLOGY

The pathophysiology of *H. alvei* has been investigated most thoroughly with regard to its production of gastrointestinal symptoms,[3] although whether *H. alvei* is actually a diarrheagenic pathogen remains controversial. Albert and associates[4] showed that although *H. alvei* elaborated neither enterotoxins nor a Shiga-like toxin and was not invasive in HeLa cell assays or by Sereny test it did produce diarrhea in experimental animals whether given parenterally or by mouth. Sections of intestines from infected animals showed lesions indistinguishable from those caused by enteropathogenic *Escherichia coli.* "Diarrheagenic strains" of *H. alvei* also were thought to differ from other strains in that they possessed the *eaeA* gene.[40] Janda and colleagues[44] first presented data suggesting that diarrheagenic *H. alvei* isolates were actually either unusual biotypes of *E. coli* or a new species in the genus *Escherichia.* Subsequently, the same group showed that organisms originally called *H. alvei* reported to produce attaching-effacing lesions and to possess the *eaeA* gene are actually a novel species, *Escherichia albertii.*[39] *H. alvei* does cause damage to intestinal epithelial cells but does not use the attaching-effacing mechanism, nor does it use the same mechanism as *E. coli* O157:H7.[25] Information about the pathophysiology of extraintestinal infection is sparse.[43]

CLINICAL MANIFESTATIONS

Cases of diarrhea caused by *H. alvei* (possibly *E. albertii*) have been reported primarily in children.[3,4] Most patients with gastroenteritis secondary to *H. alvei/E. albertii* report 6 to 12 episodes of watery diarrhea per day, low-grade or no fever, and nausea with or without vomiting. Mucus sometimes is found in stools, but blood is not.[81,98] In most patients, symptoms last for a few days, but in some patients, symptoms persist for more than a week.[81] One patient with a reactive arthritis from *H. alvei/E. albertii* enteritis has been reported.[71] A unique case has been reported of an 11-year-old girl who had a 3-day history of red lesions on the forehead, neck, and trunk associated with abdominal pain, emesis, and decreased urinary output, with one bloody diarrheal stool the day before admission who then developed hemolytic-uremic syndrome. Stool cultures repeatedly were negative for *E. coli* O157:H7 but positive for a toxigenic strain of *H. alvei* from two consecutive cultures.[19]

Traditionally, extraintestinal *H. alvei* infections were thought to occur mostly in hospitalized patients and to be hospital acquired. In one large series, the organism was isolated from 80 samples collected from 61 patients; 57 (93%) patients had underlying illnesses, most commonly malignancies.[34] Nearly half of isolates were from the respiratory tract. Other sites included blood, skin, wounds, urine, and intra-abdominal abscesses. In 60 (75%) samples, other organisms were cultured concomitantly. In a larger study from Canada, two thirds of 138 isolates were of community onset, 112 (81%) were from the urinary tract, and 94 (68%) were from monomicrobial infections.[51] Older age and female gender were risk factors for development of infection.

One 20-day-old premature infant with necrotizing enterocolitis grew *H. alvei* from blood and stool.[32] Yeager and associates[101] reported four cases of pneumatosis intestinalis in patients after they had undergone bone marrow transplantation, and in one of the four cases *H. alvei* was grown in pure culture from blood. An 8-year-old boy with acquired immunodeficiency syndrome (AIDS) developed recurrent episodes of *H. alvei* bacteremia.[18] Both episodes were associated with fever and diarrhea; the second episode also was associated with pneumonia and pleural effusion, the cause of which is unclear. A well-documented case of pneumonia in a 54-year-old woman with AIDS has been reported in which the pleural fluid grew a pure culture of *H. alvei.*[28] A patient with graft-versus-host disease developed *H. alvei* colonization with mild symptoms suggesting infection.[85] Pyelonephritis[55] and gangrenous cholecystitis[76] have been reported. A 39-day-old infant without obvious risk factors developed urosepsis.[54] A single case report of *H. paralvei*

bacteremia, in an 85-year-old man, exists. His culture was also positive for an enterococcus.[75]

Wound abscess caused by *H. alvei* has been reported.[1] A 2-year-old liver transplant recipient developed hepatic abscess and bacteremia with *H. alvei* and *Enterococcus faecalis*.[8] One case of meningitis in a 1-year-old infant without known predisposing risk factors has been reported.[67] A case of a woman with rheumatoid arthritis who contracted endophthalmitis with *H. alvei* in mixed culture has been described; the woman used snake powder as a food seasoning.[13] Two case reports are described in the older literature of persistent bacteremia with this organism, alone and in mixed cultures. One of these patients was a previously well 13-year-old girl.[33]

DIAGNOSIS AND TREATMENT

Diagnosis is established by isolation of the organism from stools or from normally sterile body fluids. Gunthard and Pennekamp[34] reported the susceptibility results of 80 *H. alvei* isolates recovered from 61 patients over a 2½-year period. All isolates tested were susceptible to ciprofloxacin. Isolates also were generally susceptible to tobramycin (99%), imipenem (99%), piperacillin (92%), trimethoprim-sulfamethoxazole (90%), ceftriaxone (88%), and ceftazidime (88%). Nearly all isolates were resistant to ampicillin and to amoxicillin-clavulanate.

H. alvei is constitutively cephalothin resistant.[98] One report describes an inducible β-lactamase that rendered the isolate ceftazidime-resistant.[91] In a study of 17 isolates from a single institution in France, 6 were noted to have a high-level constitutive, inducible cephalosporinase production profile similar to that of *Enterobacter* spp.[50] In one study, the antimicrobial susceptibility of *H. alvei* was compared with that of *E. albertii*, the organism with which *H. alvei* is confused most frequently. *E. albertii* isolates were naturally susceptible to all β-lactams except for penicillin and oxacillin; they also were susceptible to azithromycin. In contrast, *H. alvei* strains were naturally resistant to tetracycline, amoxicillin, amoxicillin-clavulanate, ampicillin-sulbactam, azithromycin, and the narrow-spectrum cephalosporins.[88]

Treatment probably is unnecessary for most cases of gastroenteritis. Treatment of invasive infection should be based on susceptibility testing. Empirical therapy with a third-generation cephalosporin and an aminoglycoside is reasonable pending susceptibility results.

PANTOEA AGGLOMERANS

First identified as a plant pathogen and named after Erwin Smith in 1917, the genus *Erwinia* has an extended domain as an infectious microbe, including production of disease in humans.[12,79,87] A member of this group of organisms, *Pantoea agglomerans (Enterobacter agglomerans, Erwinia herbicola)* has been established as a cause of conjunctivitis,[12] central nervous system infections,[12,84] urinary tract infections,[78,83] pneumonia,[2] and nosocomial infections secondary to contaminated intravenous fluids.[31,48]

BACTERIOLOGY

Species definition within *Erwinia* has been controversial and confusing. It has been suggested to rename the anaerogenic clinically relevant *Erwinia herbicola-lathryi* group *E. agglomerans* or *P. agglomerans*.[27,41,87] In clinical microbiology, both of the latter terms tend to be used interchangeably. This species consists of facultatively anaerobic, fermentative, hydrogen sulfide–negative, gram-negative rods; they do not possess oxidase, phenylalanine deaminase, proteinase, or arginine dehydrolase.[27] None decarboxylates ornithine.[41] They are motile, have peritrichous flagella, and produce a yellow pigment. Strains grow well at 37°C (98.6°F) on standard agar. When colonies are viewed microscopically after growth for 18 to 20 hours, characteristic biconvex spindle-shaped bodies and bacterial aggregates often can be seen.[12,84] Almost all strains isolated from clinical specimens and grown on agar slants show characteristic elongated, spheroidal aggregates,[86] termed *symplasmata* by Cruickshank,[20] who first described them.

EPIDEMIOLOGY

Microorganisms of the genus *Erwinia* long have been recognized as phytopathogens producing dry necrosis, wilts, and soft rots in plants; and more recently they have been associated with disease in trout and leafhoppers.[79,87] *P. agglomerans (E. herbicola)* first was isolated in humans from stool specimens of patients with typhoid fever in the 1920s and given the name *Bacterium typhi flavum* because of the organism's alleged capacity to be transformed into *Salmonella typhi* in subculture. Identification of saprophytic human strains followed, and the biochemical and cultural identity of *B. typhi flavum* with the *E. herbicola-lathryi* group finally was established.[27]

The first reports of *P. agglomerans* as a human pathogen appeared in the 1960s. Subsequently, a nationwide outbreak of infection caused by this organism was traced to contaminated liners from caps of parenteral solution bottles.[57,58] The importance of this organism as a nosocomial cause of bacteremia is emphasized by the 17 percent mortality rate in patients receiving an infusion with the contaminated intravenous fluid.[57] A trend was noted for an increased mortality rate in infected individuals younger than 20 years old. In neonatal intensive care units, the situation seems to be even more dire; in one study, the mortality rate for infants with blood cultures

positive for *P. agglomerans* was 88 percent (seven of eight).[94] Lipid-based medications support rapid bacterial growth at room temperature and, in the absence of strict aseptic handling, have been implicated in more recent nosocomial *P. agglomerans* bloodstream infections.[10] *Pantoea* outbreaks also have been traced to contaminated blood products; prolonged storage of packed red blood cells at 4° C provides conditions that allow these organisms to grow and subsequently produce high concentrations of endotoxin.[6] Cotton used to filter heroin has been implicated as a source of infection ("cotton fever") in intravenous drug users.[29]

Outbreaks in pediatric hospitals and urgent care centers caused by contaminated intravenous solutions[62] or tubing[9] also have been described. At least one retrospective review of *Erwinia* organisms isolated from clinical specimens suggested a predisposition to infection in the pediatric age group[12]; however, other studies have noted no preference based on season, sex, age, or residence in hospitals.[87] A large pseudo-outbreak traced to contamination of cotton pledgets also has been reported.[48]

PATHOPHYSIOLOGY

The true incidence of clinical infection caused by *P. agglomerans* is difficult to ascertain because of the common association of this microbe with other organisms when obtained from clinical specimens. Nonetheless, the accumulation of case reports in which this organism is isolated in pure culture from infected material leaves little doubt that *P. agglomerans* can be a human pathogen, apart from its role as a nosocomial contaminant. This organism has little inherent invasiveness. Evidence for animal pathogenicity of *Erwinia* strains isolated from plants and humans is limited[53]; 10^{13} washed organisms injected intraperitoneally into mice or guinea pigs do not cause symptoms, whereas inoculation of 10^{27} organisms leads to death within 36 hours.[20]

Most strains seem to act as saprophytes in humans,[96] but the organism has been isolated from purulent wounds of the extremities acquired through lacerations or thorn pricks, which suggests agricultural injury as a possible mode of infection.[96] Thorn injuries also have led to septic arthritis and osteomyelitis.[21] A delay of 4 to 6 weeks often occurs between the injury and the bone or joint infection. Most serious infections have occurred in individuals with a breach of host defenses (e.g., immunocompromised individuals or patients who received contaminated intravenous fluid).

CLINICAL MANIFESTATIONS

P. agglomerans bacteremia often is associated with fever, shaking chills, and systemic toxicity characteristic of gram-negative sepsis. These symptoms frequently have been misinterpreted, however, in hospitalized patients who unknowingly were administered contaminated intravenous fluids.[58] Premature neonates with sepsis owing to *P. agglomerans* tend to have a rapidly progressive sepsis with prominent pulmonary involvement, including hemorrhage and acute respiratory distress syndrome. A case series of five premature infants with *P. agglomerans* bacteremia has been reported; all infants had a birth weight of less than 1500 g, and in all cases the onset of sepsis was after age 7 days. Lethargy, mottling, and bradycardia were common; patients had desaturations but no evidence of pulmonary disease. Thrombocytopenia developed in four of the five infants, with metabolic acidosis in two and jaundice in two.[5] In the largest pediatric series reported to date, 21 of 53 (about 40%) *P. agglomerans* isolates from normally sterile sites were grown from central venous lines; of these, two thirds were polymicrobial.[21]

Eye and skin infections caused by *P. agglomerans* are particularly prominent. Bottone and Schneierson[12] included six cases of conjunctivitis, five of which occurred in infants, from whom this organism was isolated. Only two of the isolates were in pure culture, however, and a description of the clinical course of these children was not included in the report. *Erwinia* endophthalmitis has been associated with foreign-body penetration of the eye in a 14-year-old boy.[72]

Skin infection in association with a casted fracture has been described in an elderly patient,[96] and wound infections from which this organism was isolated have been described subsequently, most often in association with agricultural injury.[96] Four isolates were obtained in mixed cultures from skin lesions of children younger than 5 years old, but their possible role in those infections was not confirmed.[12] In a recent series, 14 cases of abscesses required drainage; all 14 were polymicrobial.[21] *P. agglomerans* was the only organism isolated from six consecutive blood cultures in a 9-year-old boy with osteomyelitis.[60] A 13-year-old boy developed septic arthritis caused by *P. agglomerans* 1 month after sustaining a plant thorn injury to his knee.[22] A case of *P. agglomerans* spondylodiscitis has been reported.[79] In many cases of *P. agglomerans* osteomyelitis or septic arthritis, the patient is afebrile and blood cultures are negative. In addition, measures of inflammation and joint fluid findings may be largely unremarkable.[21] A high index of suspicion of *P. agglomerans* must be maintained when bone or joint infection follows plant thorn injury.

Primary lung disease caused by these bacteria is a rare occurrence; it has been reported in an adult with chronic bronchitis[5] and also in a heart-lung transplant recipient.[5] This organism is a very rare cause of meningitis. A contaminated incubator has been implicated in two cases of neonatal central nervous system infection,[92] and a cisternal tap revealed the presence of *P. agglomerans* in an unrelated case in a newborn whose clinical course was not described.[12] A 57-year-old man with tetralogy of Fallot and cyanosis had a brain abscess in which *P. agglomerans* organisms grew in pure culture.[97] Presenting manifestations included headaches, seizures, and left-sided weakness, which occurred over a 2-week period before admission. The patient recovered after undergoing drainage of the abscess and gentamicin therapy. Several cases of peritonitis in patients on continuous ambulatory peritoneal dialysis have been reported[30,46,56]; in one case the infection was thought to be secondary to a rose thorn injury.[52]

DIAGNOSIS

Difficulty in identifying this organism is common; in March 1972, as part of a quality control program, *P. agglomerans* was sent as an unknown organism to 250 U.S. hospitals and was identified incorrectly 45 percent of the time.[58] Even when fully identified in isolates from human sources, *P. agglomerans* often is considered a contaminant or saprophyte. The organisms have been identified mistakenly as *Citrobacter*, *Escherichia coli*, *Flavobacterium*, and *Klebsiella*. In addition to routine microbiologic studies, identification of yellow-pigmented colonies and observation of the characteristic spindle-shaped bodies and symplasmata can aid in this differentiation. Symplasmata (elongated, spheroid aggregates) are seen best in the condensation water of slant cultures.[96] Spindle-shaped bodies termed *Wetzsteinformen* by German authors are observed best on standard agar with a low-power microscope lens.[87] Generally, speciation based on metabolic profile is problematic. A multilocus gene sequencing method for species identification and strain tracking has been described.[23]

TREATMENT

Most localized infections respond to treatment that includes an aminoglycoside. The presence of persistent localized infection with this organism should prompt a search for an organic foreign body, given the organism's tendency to live as a saprophyte or as a pathogen in vegetable material. In addition to appropriate antimicrobial therapy, treatment of bacteremia should include removal of any potentially contaminated intravenous access. The physician should be alert to the possibility of a common source of infection in nosocomial outbreaks.[58] In view of the rarity of bacteremia caused by *P. agglomerans*, single sporadic cases should be investigated, and clusters of two or more cases should lead to immediate inquiry into possible sources of contamination. Formal surveillance programs have been the key to early recognition and abortion of epidemics.[58]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 115

Aeromonas

Santhosh Nadipuram • James D. Cherry

Aeromonas spp. were recognized for their role in disease first by Sanarelli in 1891. His findings associated aeromonads with bacteremic "red leg" disease in frogs.[154] Studies by Hill and associates in 1954 linked the first human disease, acute fulminating metastatic myositis, with *Aeromonas* infection.[29] Generally, *Aeromonas* spp. have been considered opportunistic pathogens for humans; however, these organisms have been identified with increasing frequency as primary pathogens in normal individuals as well as in compromised hosts.

Aeromonas bacteria are ubiquitous. They are found as normal flora in nonfecal sewage and are isolated from tap water, canals, streams, and rivers. They also have been isolated from clinical and food samples. Aeromonads are pathogens for cold-blooded animals (fish, shellfish, amphibians, and reptiles).

EPIDEMIOLOGY

Ewing and associates[55] and other investigators have isolated *Aeromonas* from tap water and from the water or sediments of rivers, especially during periods when the water temperature was relatively warm.[88,113,159] Hazen and colleagues[74] recovered *A. hydrophila* from 135 of 147 natural water sources in 30 states of the United States and reported that its density was higher in flowing (lotic) than in calm (lentic) water systems and lower in freshwater than in saline systems; *Aeromonas* could not be recovered from waters in which the saline content approached that of sea water or from extremely polluted waters. Leclerc and Buttiaux[97] found *Aeromonas* in 30 percent of more than 9000 samples of drinking water in France. Drinking water sampling by the U.S. Environmental Protection Agency (EPA) in 2011 revealed the presence of aeromonads in 42 of 293 (14.3%) of samples of public water systems in the United States.[49] *Aeromonas* spp. also have been recovered from hospital water supplies.[113,135,136] Pin and colleagues[138] isolated these organisms from clinical and food samples, including poultry, shellfish, pork, and beef, where they thrived even at low temperatures.

Aeromonas organisms survive readily on surfaces such as bench tops and moistened paper towels. Slotnick[166] recovered *Aeromonas* organisms from a moistened paper towel that had been allowed to dry 24 hours after the application of the organisms. When the towel was placed in a humidified closed environment, the period was extended to 2 weeks.

A. hydrophila may be found in the mouths of fish, alligators, turtles, tadpoles, and frogs.[78] Studies done in Thailand and Turkey have found high percentages of *Aeromonas* in uncooked commercially sold seafood (27% of samples from Thailand, 94% of fish from Turkey).[182,185] Another investigation of fish and animal meats bought at markets in northern India revealed *Aeromonas* species in 38 of 332 (11%) food samples.[163] It also has been found in the feces of guinea pigs and laboratory mice.[47] Ticks are another source of *Aeromonas*. Unusual sources of *Aeromonas* infection include contamination of home or hospital hemodialysis equipment,[83,143] tsunami-associated wound contamination,[77] and contamination of blood or blood products.[140,144] San Joaquin and colleagues[153] noted that *Aeromonas* organisms also have been found in ornamental aquaria belonging to patients with *Aeromonas*-associated gastroenteritis; however, they found that isolates from the aquaria differed in susceptibility testing from the gastrointestinal isolates, so the aquaria probably were not the sources of infection. A multicenter study of over 150 extraintestinal clinical isolates showed the presence of 22 isolates of *A. aquariorum*, a species once believed to be only virulent to ornamental aquaria.[58]

Aeromonas also have been isolated from a large proportion of ready-to-eat salads.[109] Of *Aeromonas* salad isolates, 35 percent were *A. hydrophila* or *A. sobria*. All isolates tested in this study had at least one marker of enteropathogenicity, including hemolysin and cytotoxin production. Nonetheless, few if any, cases of diarrhea have been associated with ingestion of these salads in immunocompetent hosts.

In 1988, California made infection by *Aeromonas* a reportable condition, permitting the first population-based study of the epidemiology of infection caused by this organism. The overall incidence rate for *Aeromonas* isolation was 10.6 cases per 1 million population. The gastrointestinal tract was the most common site of infection (81% of cases), followed by wounds (9%). Five (2%) of 219 patients with *Aeromonas* infection died; all had serious underlying medical conditions.[92] Studies of traveler's diarrhea revealed the presence of *Aeromonas* spp. in 8 of 56 (14%) stool samples in Thailand.[35] A retrospective review of diarrhea in neonates in Bangladesh showed the presence of *Aeromonas* spp. in 222 of 699 stool samples that were positive for bacteria (222 of 2511 overall), making it the second most common isolate after *Vibrio cholerae* in this cohort.[91] A study involving patients with diarrhea in Spain showed *Aeromonas* spp. in 32 of 800 (4%) diarrheal stools.[129] The bacteria isolated were found to be similar (by pulsed-field gel analysis) to isolates from drinking water isolates. Data from a study in southern Brazil using 680 stool samples from patients with

diarrhea compared with 300 healthy controls showed that 2.6 percent of the diarrheal samples contained *Aeromonas*, whereas only 0.3 percent of the control samples contained this organism.[172] *A. hydrophila* has been placed on the EPA's contaminant candidate list of emerging pathogens in drinking water because it has the potential to grow in water distribution systems and to be resistant to chlorination.[20]

ETIOLOGIC AGENT

Aeromonas organisms are motile, asporogenic, gram-negative rods that contain a single polar flagellum. The organisms are oxidase positive and catalase positive and produce acid or gas during carbohydrate fermentation. They can grow at temperatures between 0°C and 41°C. Growth may occur within a pH range of 5.5 to 9. Lipase, gelatinase, DNase, and other exoenzymes are formed by these organisms.[54,158,179]

Aeromonads grow well on blood agar; most strains produce a large zone of β-hemolysis on this medium, although nonhemolytic strains exist. *Aeromonas* colonies on blood agar have a ground-glass appearance and a fruity odor.[181] Aeromonads also grow on MacConkey, eosin-methylene blue, *Salmonella-Shigella*, and triple-sugar iron media.

The sensitivity and specificity of various media for detection of *Aeromonas* spp. in fecal specimens have been evaluated.[122,148,178] Isolation is achieved readily on any of the following: Pril-xylose-ampicillin agar, xylose-sodium, deoxycholate citrate agar, alkaline peptonic water, inositol–brilliant green bile salts agar, trypticase soy broth with ampicillin, and dextrin-fuchsin-sulfite agar.[178] The colonies appear almost colorless on these media, with the exception of growth on dextrin-fuchsin-sulfite agar, on which they appear dark red.

Mishra and associates[117] evaluated five selective agars. Of these, sheep blood agar with 30 mg of ampicillin per liter (ASBA 30) permitted the greatest number of *Aeromonas* colonies to grow while also inhibiting the competing fecal flora. These researchers recommend that ASBA 30 be used with DNase–toluidine blue agar (DNTA) to detect the ampicillin-susceptible strains and the nonhemolytic strains. The combination of ASBA 30 and DNTA allowed 98 percent of all isolates to be detected.

Strains of motile *Aeromonas* isolates can be identified to species level by use of the following tests: production of nitrate reductase; fermentation of D-glucose and trehalose; failure to use mucate; and the inability to produce acid from D-arabitol, dulcitol, erythritol, and xylose.[1] More recently, the use of restriction fragment length polymorphism analysis of the 16s RNA, along with gene sequencing of common genes has contributed to the speciation of *Aeromonas* isolates.[58] Detection of *Aeromonas* organisms by use of strain-specific fluorescent antibody has been described.[178] The technique is not satisfactory; only a small percentage of isolates react with prepared antisera, which suggests the presence of numerous serogroups. The use of a monoclonal antibody against *A. hydrophila* has been shown to overcome this problem, however.[46] This monoclonal antibody could prove beneficial in the future as a screening tool. Additionally, the study of selected housekeeping genes has been helpful in establishing phylogenetic relationships among members of the aeromonads.[169]

Aeromonas previously was considered a member of the Vibrionaceae, which included the genera *Vibrio* and *Plesiomonas*.[141] Molecular genetic techniques have identified that these three genera are not related evolutionarily, however, and aeromonads represent a family of their own.[41] *Aeromonas* have long been viewed as belonging to one of two major groups on the basis of their ability to grow at different temperatures. Mesophiles were strains that grew at 35°C to 37°C, and psychrophilic strains were more prevalent at lower temperatures (22°C to 28°C). These two groups could be distinguished not only by optimal growth conditions but also by elaboration of pigmentation on tyrosine agar and production of indole. The mesophilic strains are motile, and the psychrophilic strains are nonmotile.

Twenty-two *Aeromonas* spp. have been recognized, and this number is expected to increase as new strains are isolated and identified.[1,132] Although the number of strains of psychrophilic *Aeromonas* spp. has remained stable, the number of various strains of mesophilic species isolated has increased. Several classification schemes within the genus are in use. The strains are classified based on biochemical assays or the use of genotyping techniques such as DNA-DNA hybridization and restriction fragment length polymorphism of the 16S rRNA, or both. Genetic techniques have been used to differentiate the genus into genomospecies or hybridization groups (HG), allowing more precise identification.[21]

Abbott and associates[1] classified *Aeromonas* based on the results of the Møeller decarboxylase and dihydrolase reactions. They also were able to place the strains they studied into complexes based on certain biochemical reactions. The *Aeromonas* strains that produced elastase, pectinase, and stapholysin were grouped into the *A. hydrophila* complex (*A. hydrophila*, *A. bestiarum*, and *A. salmonicida*). Similarly, the *A. caviae* complex includes *A. caviae*, *A. media*, and *A. eucrenophil*, and the *A. sobria* complex comprises *A. veronii* HG8, *A. jandaei*, *A. schubertii*, and *A. trota*.

In addition, other species, including *Aeromonas media* (similar to *A. salmonicida*),[6] *A. veronii*,[76] *A. schubertii*,[28,75] *A. jandaei*,[27] *A. trota*,[26] *A. allosaccharophila*,[107] *A. encheleia*,[53] *A. bestiarum*,[8] *A. popoffii*,[81] and *A. eucrenophila*,[158] have been described. A new species, *A. culicicola*, was isolated more recently.[137] Other isolates include *A. enteropelogenes* and *A. ichthiosmia*, which seem to be similar to previously identified species.[40] Of the species isolated currently, *A. hydrophila*, *A. caviae*, and *A. veronii* have been associated most often with human infections.[115]

Aeromonas is confused most frequently with Enterobacteriaceae. The oxidase test always should be performed to aid in differentiation; *Aeromonas* organisms generally are oxidase positive, whereas the Enterobacteriaceae are oxidase negative. McGrath and associates[111] described oxidase-variable strains of *A. hydrophila*. These strains are oxidase positive when grown on nonselective media but oxidase negative when grown on differential or gram-negative media. Organic acid end-products of

lactose fermentation can inhibit the oxidase reaction. Paik[130] also has shown that a platinum wire loop should be used for oxidase testing; use of an iron-containing loop can cause false-positive oxidase results.

Aeromonas has traditionally shown susceptibility to ceftriaxone (8 μg/mL), chloramphenicol (2 to 4 μg/mL), gentamicin (0.5 to 2 μg/mL), streptomycin (16 μg/mL), trimethoprim-sulfamethoxazole (<0.5/9.5 μg/mL), and imipenem and meropenem.* Reinhardt and George[146] determined that the most active on a weight basis were ciprofloxacin, enoxacin, and norfloxacin; nalidixic acid and trimethoprim-sulfamethoxazole also possessed good activity. Neither sulfamethoxazole nor trimethoprim alone was active. In addition, these investigators did not note appreciable differences in susceptibility among species or in susceptibility between fecal versus nonenteric isolates. In contrast, Motyl and colleagues[121] noted higher levels of resistance to various antibiotics among *A. hydrophila* strains compared with *A. sobria* or *A. caviae*, as judged by minimal inhibitory concentration. Susceptibility to cephalothin may serve as a useful criterion in the identification of *A. sobria*.[121,153] Resistance to fluoroquinolones has been shown to be based on chromosomal mutations of the *gyrA* and *parC* genes,[2,7] along with a plasmid containing a *qnrS* gene[9,10,73] and a separate plasmid with the aac(6′)-Ib-cr.[57]

Aeromonas organisms consistently are resistant to penicillin, ampicillin, carbenicillin, cephalothin, erythromycin, clindamycin, and vancomycin. Sawai and associates[157] showed that resistance to β-lactam antibiotics is caused by the production of a species-specific, chromosome-mediated β-lactamase. Two studies of *Aeromonas* spp. cultures examining for the presence of the *cphA* gene encoding for metallo-β-lactamase have been published. In Brazil, 87 *Aeromonas* isolates recovered from environmental sources showed a prevalence of the *cphA* gene in 97.6 percent of *A. hydrophilia* isolates and 100 percent of *A. jandaei* isolates. Likewise, 51 consecutive blood isolates of *Aeromonas* spp. were examined and found that overall, *cphA* was present in 69 percent of these isolates. The rise of these resistant strains of *Aeromonas* spp. is very troubling.[12,183] Tetracycline resistance was found in environmental and fish isolates of *Aeromonas* by Han and colleagues.[72] This resistance was conferred by several *tetA* through *tetE* genes; *tetE* was found on a plasmid. It is not R plasmid mediated. In 1980, McNicol and coworkers[112] reported the recovery of *Aeromonas* isolates from the Chesapeake Bay that were resistant to tetracycline and polymyxin B. They also noted that 57 percent of isolates from Bangladesh had a multiple streptomycin-chloramphenicol-tetracycline resistance phenotype that correlated with the presence of a larger plasmid.

PATHOGENESIS

In addition to its pili, *A. hydrophila* produces numerous virulence factors, including extracellular toxins and enzymes that are involved in the pathogenesis of *A. hydrophila* infection. Some of the toxins elaborated by *A. hydrophila* include hemolysins, aerolysin, and enterotoxins.[15] Like many other gram-negative bacteria, *Aeromonas* spp. employ a type III secretion system to bind to host cells and deliver toxins.[2]

α-Hemolysin is released from cells during a stationary growth phase. It has a molecular weight of 50[101,102] to 65[101] kDa and is stable at room temperature between pH 3.5 and 9.5. It is heat labile and is cytotoxic to HeLa cells and human embryonic lung fibroblasts.[177] When injected into rabbit skin, it causes dermonecrosis. Intraperitoneal injection of α-hemolysin is lethal for rabbits and mice.

β-Hemolysin has a molecular weight of 49 to 53 kDa and is released near the end of the logarithmic phase of growth of the *Aeromonas* organism. It is heat labile and resists destruction by trypsin and pronase.[102] It causes dermonecrosis of rabbit skin and is lethal for rabbits, rats, and mice. It is cytotoxic to HeLa cells and to human diploid lung fibroblasts.[175] It also has been shown to induce impairment in the intestinal epithelial barrier and to stimulate active chloride secretion in human colon cell monolayers, contributing to enteritis.[52]

α-Hemolysin and β-hemolysin may be significant virulence factors. Most clinical isolates are β-hemolytic, and hemolysis is a common feature of infection caused by *Aeromonas* spp. α-Hemolysin and β-hemolysin in high concentrations produce hemorrhagic enteritis in a rabbit ileal loop; however, neither is clearly established as a virulence factor in diarrheal disease.[103] Antibodies to either hemolysin neutralize both toxins.

Aerolysin is a pore-forming toxin that shares some homology with β-hemolysin.[52] After inserting into its target cells, it disrupts ion gradients and membrane potentials, leading to cell lysis.[96] Caco-2 cells derived from human intestine have been shown to be very sensitive to the effects of aerolysin.[3]

In 1975, Sanyal and associates[155] showed that the enterotoxins from *A. hydrophila* were enterotoxigenic. Subsequently, enterotoxigenic *A. hydrophila* has been isolated from humans,[25,65-68,88,180] water sources,[15] fish, and pigs.[22,127] Sha and colleagues[160] have characterized three enterotoxins from *A. hydrophila.* The cytotoxic enterotoxin has hemolytic, cytotoxic, and enterotoxic activities and has a molecular weight of 52 kDa. It is a pore-forming toxin that has been shown to cause fluid secretion and tissue damage in mouse ileal loops.[96] The other two are cytotonic enterotoxins. One has a molecular weight of 44 kDa and is heat labile. The second has a predicted molecular weight of 71 kDa and is heat stable. These cytotonic enterotoxins cause elevation of cyclic adenosine monophosphate and prostaglandin levels in Chinese hamster ovary cells and fluid secretion in rabbit ileal loops.[160] All three enterotoxins have been implicated in *A. hydrophila*–induced gastroenteritis. *Aeromonas* spp. also produce proteinase A and B, endopeptidase, staphylolytic enzyme, fibrinolysin, and leukocidin.[101] The precise relationship of these toxins and enzymes to the pathogenesis of human infection is unclear.

Strains of *Aeromonas* produce proteases, DNase, lecithinase, and elastase.[4] These extracellular enzymes may have pathologic significance. *Aeromonas* strains that possess hemolytic and cytotoxic capabilities and that are characterized as HG1/BD-2 type strains have been

*References 12, 55, 56, 127, 128, 145, 178.

related strongly to patients with diarrheal disease.[95] Human *Aeromonas* isolates have been found also to express Shiga toxins (much like Shiga toxin–producing *Escherichia coli*).[9]

Antihemolysin and agglutinating and precipitating antibodies to *A. hydrophila* have been detected in patients with systemic *Aeromonas* infections but not in patients with superficial infections. Increases in the antihemolysin titer to 1:1280 and in the agglutinin titer to 1:640 have been noted.[30]

Burke and colleagues[24] found that many strains associated with diarrhea were able to hemagglutinate cells from human, horse, rat, and guinea pig. Of these strains, 68 percent displayed fucose-resistant hemagglutination. The investigators suggested that these properties may contribute to virulence. The ability of *Aeromonas* spp. to create biofilm allowing for colony protection and quorum sensing has been demonstrated.[33,50]

Ketover and associates[89] showed that normal serum promotes phagocytosis and intracellular killing of *Aeromonas* organisms by normal white blood cells. In contrast, sera from two patients with fatal *Aeromonas* infections failed to do so. One patient had an increase in the serum opsonic antibody titer from less than 1:5 in the acute stage of disease to 1:5120 in the convalescent stage. These studies suggest that a specific opsonizing antibody that is present in normal serum and normal bactericidal activity of neutrophils are required to prevent invasive *A. hydrophila* infections.

The flexible type IV pili of *Aeromonas* are the predominant pili expressed on fecal isolates of diarrhea-associated species of *Aeromonas.* They represent a family of type IV pili that has been designated Bfp (bundle-forming pili). Kirov and associates[93] have presented compelling evidence to support the concept that Bfp are important intestinal colonization factors. More recently, this group also showed that *Aeromonas* flagella are adhesins for human intestinal cells, playing a role in its enteropathogenicity.

Serogroup analysis may be helpful in establishing which *Aeromonas* isolates can cause human disease. Serogroups O:11, O:34, and O:16 predominate as causes of clinical infection.[82] Hadi and colleagues successfully isolated a 22-kb region of the *A. veronii* bv. *sobria* genome, demonstrating many functions of the Bfp subunits by mutations.[71]

Clear correlation between known virulence properties and enteropathogenicity in humans is lacking. This lack of a clear correlation has been attributed to the heterogeneity of *Aeromonas* spp., the great variety of *Aeromonas* virulence factors, and the loose association between virulence factors and the phenotype and genotype.[115] Consequently, many researchers have proposed a multifactorial pathogenesis with the involvement of numerous cellular and extracellular virulence factors.[36]

CLINICAL MANIFESTATIONS

Aeromonas spp. have been implicated as a cause of septicemia, gastroenteritis, peritonitis, skin and wound infections, osteomyelitis, septic arthritis, ocular infections, myositis, urinary tract infections, pneumonia, meningitis, and hemolytic-uremic syndrome in children. Most of these infections have been noted in normal and compromised hosts.[14,19,59,133,134]

Sepsis caused by *Aeromonas* spp. has been reported in children.* Because *Aeromonas* infection is not a reportable disease, the total number of affected children is unknown. Although septicemia caused by *Aeromonas* spp. has occurred in normal children, most children affected have had a disorder known to impair the normal host response to infection or a disorder in which the intact skin as a barrier to infection has been destroyed. *Aeromonas* infection has been noted in children with leukemia (particularly those with neutropenia), aplastic anemia, cirrhosis, hemoglobinopathies, malnutrition, burns, and renal failure. Neonates are susceptible to sepsis when exposed to contaminated water. Chaudhari and Todd detailed neonatal sepsis, necrotizing enterocolitis, and death associated with *A. hydrophilia* in a 27-week-gestation neonate born in a toilet.[34]

The clinical manifestations of septicemia are similar to the manifestations noted in other gram-negative enteric bloodstream infections with high fever and shock. During the course of septicemia in some of these patients, ecthyma gangrenosum also has been noted. The reported case-fatality rate of 50 percent despite administration of antibiotic therapy presumably is related to the severity of the underlying disorders and not to an unusual virulence of the organism. The propensity for infection in the compromised host suggests that *Aeromonas* organisms are of low virulence for the human host. Bacteremia with *A. sobria*, *A. punctate*, *A. veronii*, *A. caviae*, and *A. schubertii* also has been described.[37,83,87,144,165]

Meningitis caused by *Aeromonas* spp. also has been reported in children.[60,61,184] In one reported review of 21 years' experience with gram-negative bacillary meningitis, *Aeromonas* spp. accounted for 2 percent of the cases.[177] The course was fulminant, and the patients died despite having received antibiotic therapy. All of these children could be considered immunocompromised as a result of sickle-cell anemia (a 23-month-old child) or age (neonates).

Gastrointestinal infections caused by *Aeromonas* spp. have been reported with greater frequency in pediatric patients. *A. hydrophila*, *A. sobria*, *A. caviae*, and *A. punctata* have been recovered from stool specimens of patients with gastroenteritis.[25,32,62,83,120] In 1961, Martinez-Silva and colleagues[108] described an epidemic of enteritis in a newborn nursery affecting nine infants (eight as neonates and one at 7 days old). *Aeromonas* spp. were found in the stools of six of these infants. One neonate, the only patient with a pure growth of *Aeromonas* in a stool specimen, died. In 1964, Rosner[150] reported severe gastroenteritis in a child with growth of *A. hydrophila* from four stool cultures. In 1991, one study reported 224 cases of *Aeromonas* gastroenteritis in Iowa from January to June.[142] Taneja and associates[173] described an outbreak of diarrhea caused by *Aeromonas* spp. on a hematology-oncology ward in a pediatric hospital during March-April 2001 where 6 of 18 children were infected. *Aeromonas* spp.

*References 23, 39, 44, 69, 80, 89, 124, 133, 149, 156, 181, 184, 186.

were found to be the sole enteropathogen in five of the six children. Aeromonads have been detected worldwide as the sole pathogen causing diarrhea in 2 to 20 percent of affected children and in only up to 2 percent of children without diarrhea.[36,43,68,174]

In an attempt to assess the role of *Aeromonas* spp. in diarrheal disease, numerous investigators have evaluated the fecal carriage rate of the organism.[70] Freij[61] described a study performed by other investigators who recovered *Aeromonas* from none of 300 adults and from 31 of 4426 (0.7%) children younger than 2 years of age. Pitarangsi and coworkers[139] reported carrier rates of 16 to 27 percent in various districts in Thailand and noted the same frequency of *A. hydrophila* in stools of Thais with and without diarrhea. In contrast, *A. hydrophila* was recovered from the stools of American Peace Corps volunteers more frequently when they had diarrhea than when their stool frequency was normal.[35] Only three *Aeromonas* isolates were reported from 1685 rectal swab cultures obtained from 1217 children hospitalized for gastroenteritis in Manitoba, Canada. Bhat and colleagues[16] recovered *Aeromonas* organisms from 7 of 133 patients with acute diarrhea in a valley in India and found *Aeromonas* and *Plesiomonas shigelloides* in the well water commonly used by these individuals. Soltan Dallal and Moezardalan[170] isolated *Aeromonas* spp. from 14 of 310 Iranian children in a case-control study. A large, retrospective study on the island of Crete found a prevalence of *A. hydrophilia* to be 0.44 percent in submitted stool cultures from children over an 18-year period.[106]

Gracey and associates[66,67] described a prospective study in Australia of 1156 children with diarrhea and an equal number of age- and sex-matched control subjects. Enterotoxigenic *Aeromonas* organisms were isolated from 10.2 percent of children with diarrhea compared with 0.6 percent of healthy children. *Aeromonas* was the only potential pathogen recovered in 6.5 percent of children with diarrhea. Cases of *Aeromonas* infection peaked during the summer months. The mean duration of diarrhea was 15.3 days, and 33 percent of the children required hospitalization. These investigators described three clinical syndromes of *Aeromonas* gastroenteritis: (1) watery diarrhea, vomiting, and low-grade fever in 41 percent; (2) diarrhea with blood and mucus in 22 percent; and (3) prolonged diarrhea of more than 2 weeks' duration in 37 percent.

Many investigators[5,31,123,125,152] have attempted to describe gastrointestinal infections caused by *Aeromonas* spp. Gluskin and associates[63] performed a 15-year study of the rate of *Aeromonas* spp. in gastroenteritis in hospitalized children. A total of 146 strains of *Aeromonas* spp. were isolated from 32,810 fecal specimens from 13,820 hospitalized patients. These isolates constituted 4 percent of all pathogenic bacterial strains cultured. Most of the cases of diarrhea (94%) occurred in children younger than 3 years old. The peak incidence occurred in infants aged 2 to 6 months. Bloody diarrhea occurred in 7 percent of children. Several investigators[5,152] have detected a larger number of cases of *Aeromonas*-associated diarrhea in the summer months than in other months, whereas Challapali and colleagues[31] found no seasonal patterns of *Aeromonas* isolation. The greatest number of cases occurred in children younger than 12 months to 3 years of age.

Symptoms included diarrhea, bloody stools, vomiting, abdominal cramps, mild dehydration, and fever. *Aeromonas*-associated diarrhea resembled other types of bacterial diarrhea, except that fecal leukocytes were absent in children with *Aeromonas*-associated diarrhea; in contrast, fecal leukocytes were found in 60 percent of children with other types of bacterial enteritis.[31] A cholera-like illness caused by enterotoxigenic *A. sobria* has been described.[32] Gastroenteritis caused by *A. sobria* and *A. hydrophila* tended to be acute, whereas diarrhea associated with *A. caviae* frequently was chronic, lasting 4 to 6 weeks in untreated patients.

San Joaquin and Pickett[152] described three patients with *A. caviae* diarrhea who originally presented with failure to thrive presumed to be secondary to formula intolerance. Diarrhea in these patients improved after administration of trimethoprim-sulfamethoxazole. Moyer[123] noted that although *A. caviae* is considered nonpathogenic, five pediatric patients with otitis media who were treated with penicillin or ampicillin subsequently developed diarrhea in which *A. caviae* was the only potential enteric pathogen. The prior therapy with antibiotics to which *Aeromonas* spp. are known to be resistant probably contributed to colonization of the gastrointestinal tract with *A. caviae* and subsequent development of diarrhea. These four patients also were treated successfully with trimethoprim-sulfamethoxazole.

Outbreaks of diarrhea associated with *Aeromonas* in daycare centers have been described.[43] *A. caviae*, *A. hydrophila*, and *A. sobria* were the strains recovered most commonly.

Complications of *Aeromonas* intestinal infection included gram-negative bacteremia, intussusception, internal hernia strangulation, hemolytic-uremic syndrome,[19,118,147] and failure to thrive. Peritonitis has been reported in a 5-year-old patient with a ruptured appendix.[80] No additional clinical information about this patient was provided. Peritoneal dialysis catheter–related peritonitis was described in one patient.[100] The patient was involved in gardening and had poor adherence to peritoneal dialysis protocol and hand washing guidelines.

A. hydrophila has been recovered from the skin or from wound infections of children.* Most of these patients have been normal hosts; three had leukemia. In 40 percent of these cases, *Aeromonas* organisms were not recovered from the lesion in pure culture. The lower extremity was involved in 75 percent of these cases. Exposure to water was noted in 40 percent of these cases; alligator bites, snake bites, stepping on glass, and burns were other presumed predisposing factors. Clinical manifestations included cellulitis, hemorrhagic blebs, and purulent diarrhea with fever and leukocytosis. Secondary bacteremia and osteomyelitis have been reported.[18,79] In a study of neonates with omphalitis in Karachi, Pakistan, 19 of 583 (3.2%) of purulent secretions from umbilical stumps yielded a positive culture with *Aeromonas* spp. The clinical implications of the presence of *Aeromonas* in these neonates was not discussed.[116]

*References 13, 18, 45, 59, 80, 89, 110, 124, 134, 147, 161, 171, 178.

Aeromonas organisms have been recovered from skin lesions that have been the result of tick bites.* In each of the cases, a circumscribed area of purple discoloration has surrounded the bite and nonpurulent drainage from the center of the lesion yielded the organism. These patients sought medical attention because the local lesion had persisted or had increased in size over the course of 1 to 2 weeks. *A. schubertii* also has been isolated from traumatic wound infections.[28]

Ecthyma gangrenosum caused by *A. hydrophila* has been described in several children with leukemia.[89,124,161] Ecthyma gangrenosum has been seen in several children with *Aeromonas* septicemia who have had malignant or hepatobiliary disease. Clark and Chenoweth[38] isolated *A. hydrophila* from an 18-month-old boy and a 2-year-old boy, both of whom had liver transplants for biliary atresia and subsequently developed cholangitis. In both instances, these were polymicrobial infections.

Current practice by plastic surgeons to use medicinal leeches to control venous congestion after reimplantation of limbs or closure of skin flaps has led to sepsis and skin and soft tissue infection with *Aeromonas* spp. in adults.[99] This practice is now becoming more prevalent in children, and practitioners should be aware that therapy with leeches requires antibiotic prophylaxis. Leeches can harbor *Aeromonas* spp. resistant to the prophylaxis of choice.

Lopez and associates[104] described an 8-year-old child with acute myelogenous leukemia with bacteremia and osteomyelitis; *Aeromonas* organisms grew from a bone aspirate of this patient. Blatz[18] reported finding osteomyelitis and *Aeromonas* bacteremia in a previously healthy 16-year-old patient; a bone aspirate was not attempted. Septic arthritis caused by *A. hydrophila* also has been described in a child with leukemia; the organism was recovered from the second metacarpophalangeal joint at autopsy.[44] Elwitigala and colleagues[51] also recovered *A. hydrophila* in a previously healthy 13-year-old girl who developed severe septic arthritis of the knee after injury sustained in a private freshwater lake. This infection frequently is rapidly progressive.

Aeromonas has been recovered from the conjunctiva of a previously healthy 7-year-old boy whose eye had been penetrated by a safety pin[168] and from the anterior chamber of an 8-year-old boy who developed endophthalmitis after receiving a corneal laceration from a fishhook.[39] *A. sobria* endophthalmitis has been described in a 14-year-old patient after a penetrating eye injury occurred in which a cormorant pecked the patient's eye.[98]

Although numerous cases of *Aeromonas* urinary tract infections have been reported in adults, only a few cases have been reported in children. McCracken and Barkley[110] reported the recovery of *A. hydrophila* in pure culture from the urine of a 5-month-old boy with diarrhea. Bartolomé and colleagues[13] described a case of urinary tract infection associated with diarrhea in a male neonate with bilateral ureterohydronephrosis and bladder involvement from posterior urethral valves. Ojeda-Vargas and associates[126] reported the case of an 18-year-old girl with severe pyelonephritis requiring admission to an intensive care unit: *A. hydrophila* and *Pseudomonas* were isolated from her urine cultures. In a case series of seven patients with *Aeromonas* urinary tract infections in a hospital in Puducherry, India, one 4-year-old girl with chronic renal failure was found to grow *A. caviae* from a urine specimen.[105]

Myositis caused by *Aeromonas* also has been described in children. A 9-year-old girl and a 16-year-old boy required amputation of their legs as a result of *Aeromonas* myositis.[45,167] Another case of sepsis accompanied by myositis of the thigh was described by Papadakis and associates in a 2½-year-old girl with acute lymphoblastic leukemia; this child recovered well with prompt antibiotic therapy and surgical débridement.[131] Necrosis of muscle was noted in both cases, and gas was seen on the radiographs before amputation in the 9-year-old girl. Fatal myofascial necrosis also has been reported in a patient with a history of aplastic anemia.[64] *A. hydrophila* also has been isolated from abscesses caused by snake bites.[84]

Pneumonia caused by *A. hydrophila* is a rare event in children. Kao and associates[86] reported that there have been a total of seven case reports in the literature so far, and four patients died of fulminant disease. Of the seven patients, four had accompanying medical conditions, including acute leukemia (two patients), cavernous hemangioma with thrombocytopenia (one patient), and nephrotic syndrome (one patient). One patient was the victim of a near-drowning, and two patients were previously healthy.[86,145,164] One of the previously healthy patients was described by Kao and associates[86] in their case report and literature review. The patient was a 5-year-old girl who presented with fulminant sepsis and pneumonia and quickly died. *A. hydrophila* was recovered from her blood, endotracheal aspirate, and postmortem pleural fluid. Neither a bone marrow aspirate nor an immunologic workup was performed, so whether she had an underlying malignancy or immunodeficiency that might have contributed to her rapid demise is unknown. *A. hydrophila* has been isolated from lung abscess at autopsy of a 16-year-old girl with *A. hydrophila* septicemia and leukemia.[44]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Aeromonas should be considered a possible cause of infection in children with any of the disorders previously noted. In addition, *Aeromonas* infection should be considered in any child noted to be exposed to a contaminated water source (e.g., sewage, waste). It also always should be included as a possible cause of gastroenteritis, bacteremia, and skin infection in a compromised host. Generally, *Aeromonas* organisms are recognized only when they grow from body fluids or tissues that normally are sterile. Also, as noted earlier, *Aeromonas* infection should be suspected in ill children after the use of medicinal leech therapy in surgery or subsequent to an alligator bite. The best methods for isolation of *Aeromonas* organisms have been described (see the section on etiologic agent).

*Feigin RD, unpublished data.

A. hydrophila in food can be detected by an enzyme-linked immunosorbent assay and polymerase chain reaction.[17,114,176] These organisms also have been identified in environmental samples by use of 16S rDNA–targeted oligonucleotide primers.[48] Many sophisticated techniques, including rRNA sequencing, DNA-DNA reassociation techniques, and polymerase chain reaction, have been used to continue to identify and differentiate *Aeromonas* spp.[21,42,90,115]

TREATMENT AND PROGNOSIS

Penicillin-hydrolyzing β-lactamases have been detected in most strains of *Aeromonas*, rendering those strains resistant to ampicillin.[119] Piperacillin shows variable activity against *Aeromonas* spp., whereas ticarcillin-clavulanate generally is active. In vitro, *Aeromonas* organisms generally are susceptible to chloramphenicol, aminoglycosides, trimethoprim-sulfamethoxazole, aztreonam, quinolones, and the third-generation cephalosporins.[85,94,151] Great care must be taken to obtain minimal inhibitory concentrations on *Aeromonas* isolates, and carbapenems should be initiated when there is lack of clinical response, because extended-spectrum β-lactamase–producing organisms are known to occur both in the environment and in clinical isolates.[12] Likewise, rates of tetracycline, fluoroquinolone, and aminoglycoside resistance should be known before considering these agents.[2,10-12,73,162]

Initial empirical treatment with a third-generation cephalosporin is suggested. Following this, a drug to which the organism is sensitive should be provided (usually intravenously). The duration of administration depends on the site of infection and the clinical response to therapy. The occurrence of *Aeromonas* infections predominantly in compromised hosts accounts for the high case-fatality rate despite administration of an antibiotic agent to which the organism is susceptible.

CHAPTER 116

PASTEURELLA MULTOCIDA

Barbara W. Stechenberg • Kathy Pinkerman

In 1878, Kitt first isolated a bacterium of the *Pasteurella* group from wild hogs during an epidemic; 2 years later, Pasteur described the organism that causes fowl cholera. Since that time, the same organism has been implicated in rabbit septicemia, swine plague, hemorrhagic septicemia, and wildseuche (a fatal disease in deer). Hueppe applied the term *hemorrhagic septicemia* to this group of infectious diseases in lower animals because of the characteristic hemorrhagic areas scattered throughout most of the viscera. Original names for the causative organisms included *Pasteurella aviseptica*, *Pasteurella boviseptica*, *Pasteurella suiseptica*, and *Pasteurella lepiseptica*, but these organisms now are classified under the name *Pasteurella multocida*, a small, nonmotile, gram-negative rod.[40]

Although *P. multocida* primarily is a pathogen in animals, recognition of its potential for infection in humans has been increasing. Brugnatelli reported the first bacteriologically proven case in a human in 1913. Schipper[41] did an extensive review of the literature from 1930 through 1947 and reported only 40 cases of infection with *P. multocida*. Since then, an increasing number of human infections with *P. multocida* have been reported.[43]

THE ORGANISM

P. multocida generally appears as a short, ovoid, gram-negative rod; however, it also may appear as a coccobacillus with convex sides and rounded ends. The length ranges from 0.3 to 1.25 μm, and the diameter ranges from 0.15 to 0.25 μm. *P. multocida* may appear singly or in pairs, chains, or clusters. Healthy organisms stain easily with aniline dyes and are gram negative. They may show bipolar staining, especially when smears are made directly from animal tissue or fluids. They become increasingly pleomorphic on subculture and may resemble Enterobacteriaceae in broth. They do not grow on eosin–methylene blue, MacConkey, deoxycholate, or any other bile-containing agar. They are facultatively anaerobic and nonmotile. They do not require X or V factor for growth, an important differential point in distinguishing them from *Haemophilus influenzae*.

Colonies are nonhemolytic and translucent, usually 1 to 2 mm in diameter, and generally low, convex, and butyrous. Occasionally, they may be larger and mucoid or iridescent. Colonies on blood agar are smaller, opaque, and grayish white. In broth cultures, turbidity, often with a flocculent sediment, is present.

Cultures tend to autoagglutinate in saline and have a peculiar odor described as musty, similar to semen or burning hair. They are catalase positive, usually oxidase positive, and indole positive. They usually ferment galactose, glucose, fructose, mannitol, mannose, and sucrose without production of gas. Some variability occurs in the fermentation of other sugars. They reduce nitrates but have negative urease, methyl red, and Voges-Proskauer reactions. Using fermentation reactions, Oberhofer[33] developed a biotyping system in which correlation of biotype, 61 percent A and B, was found with cat-bite isolates but not with dog-bite isolates.

The pathogenicity of the organism varies; most mucoid and smooth colony-forming strains produce a capsule and usually are highly pathogenic for mice and rabbits. The capsule is antiphagocytic, resisting intracellular killing by neutrophils.

Nielsen and Rosdahl[31] have developed a bacteriophage typing system for typing toxigenic and nontoxigenic strains. DNA hybridization studies have led to a reclassification of the genus *Pasteurella*. *P. multocida* now includes three subspecies: *P. multocida* subsp. *multocida*, *P. multocida* subsp. *septica*, and *P. multocida* subsp. *gallicida*. Of 159 strains recovered from 46 infected humans, 95 were identified as *P. multocida* subsp. *multocida* and 21 were identified as *P. multocida* subsp. *septica;* the remainder were divided among multiple other species.[17] Other less common *Pasteurella* spp. include *P. canis*, *P. dagmatis*, and *P. stomatis*. The use of serology in conjunction with DNA fingerprinting can classify isolates for epidemiologic studies.[53]

Immunity to *P. multocida* can be shown in many animals, and vaccines have been developed with known efficacy, especially in birds and cattle. The precise mechanisms involved in this immunity and, more important, in natural immunity are being elucidated. Antibodies to somatic and capsular antigenic determinants develop within 2 weeks of development of clinical infection, with the capsular antibodies being longer lasting.[5] The precise role of these antibodies in human host defenses is unclear. Woolcock and Collins[55] developed models in pathogen-free mice that may help uncover these mechanisms. The efficacy of heat-killed vaccine has been shown to be considerable when multiple doses are used. With the use of an aerogenic mouse model for the stimulation of respiratory spread, however, the protection is reduced. Local instillation of the vaccine can be used with this model to develop local antibodies, but preliminary results show protection only with modest challenge doses.[3] A footpad inoculation model may help elucidate the mechanisms in local human infections.

TRANSMISSION

The organism is found in the oral flora of many different animals; 67 percent of cats may harbor this organism in their mouths or throats.[51] Smith[42] found that *P. multocida* could be recovered from the tonsils of 54 percent of dogs and from the nose of 10 percent of dogs. Schipper[41] grew *P. multocida* from 14 percent of wild rats trapped in the Baltimore area. Hansmann and Tully[16] showed that *P. multocida* may remain as a commensal for prolonged periods in the mouth of a cat. They described a patient who had been bitten on two occasions 3 years apart by the same healthy pet cat; each time, an abscess caused by *P. multocida* developed. *P. multocida* also has been isolated from the lion, tiger, panther, buffalo, mink, and opossum.[4,20]

Although verifying the mode of transmission has been easiest when an infection has been related specifically to a pet or farm animal, many cases of infection caused by *P. multocida* have been documented despite a negative history of such exposure. Respiratory tract infection with this organism has been described in veterinarians, farmers, milkmen, and individuals employed where animal tissues are processed. A recent case series was reported of life-threatening *P. multocida* respiratory tract infections in association with palliative pet care in the home.[30]

The possibility of a reservoir of infection in humans with resultant interhuman transmission rarely has been considered. In a study of veterinary students, Smith[42] described 2 of 71 with positive throat isolations. The organisms were present in 1 student for a few days and in the other for the full 4 months of the study; both patients were asymptomatic. Several other cases of isolation of the organism from the human respiratory tract, many without associated symptoms or known animal contact, have been made.

In addition, interhuman spread by nasopharyngeal excretions, feces, and urine may occur because the organism has been recovered from these sites. The female genital tract is another potential source, especially for cases of septicemia and meningitis that occur during pregnancy and in the newborn period.

Investigators of an outbreak in a chronic disease hospital showed that *P. multocida* may be viable on a hand towel for 24 hours. Although the source in this outbreak was not established, this finding may have implications for spread in other situations, particularly for pet owners.[22]

EPIDEMIOLOGY

P. multocida has been isolated from humans in all areas of North America and Europe, with some reports coming from other areas. In the United States, it is not a reportable organism, so incidence and prevalence data are unavailable. Lee and Buhr[26] have cited a seasonal variation in the number of reported cases related to dog bites, with the highest incidence being in the fall and winter months, possibly related to increased nasal carriage in dogs during that period. Other investigators have found no seasonal differences.[9,29]

No difference in attack rate has been found between the sexes. The attack rate is higher in individuals of both sexes in very young (birth to 4 years old) and in older (>55 years old) individuals.

PATHOGENESIS AND PATHOLOGY

In animals that are stressed, a benignly parasitic strain may invade the mucous membrane on which it is carried. With highly virulent strains, a picture of hemorrhagic septicemia may develop that may be characterized by high fever, cardiac weakness, toxemia, and early death. Organisms can be cultured from the blood; autopsy findings may be minimal or include petechial hemorrhages on mucosal and serosal surfaces and in various organs. Less acute forms, such as a pneumonia with serofibrinous exudate in the interlobular septa of the lungs, a hemorrhagic gastroenteritis, and subacute and chronic infections such as otitis in the rabbit, may occur. The mechanisms by which these bacteria invade the mucosa and cause systemic disease continue to unfold. Key virulence factors are the capsule and lipopolysaccharide, with others still being identified.[17]

In humans, three major types of infections occur.[52] In the first and most common type, local infection occurs after a cat bite or scratch, a dog bite, or, rarely, the bite of another animal. Fifteen to 20 percent of dog-bite wounds and more than 50 percent of cat-bite wounds become infected. Many cases have been associated with nonbite exposure, such as licking.[11] These cases usually are characterized by a rapidly progressive, acute cellulitis with lymphangitis, local lymphadenitis, or both. Cat-bite wounds may progress to osteomyelitis of the underlying bone. This development is not because of any known predilection of *P. multocida* for the bone but because the sharp fangs of a cat deposit the organism on or under the periosteum.

The second type includes cases of chronic pulmonary infection in which the organism may be the only isolate or one of several organisms. Cases of bronchiectasis and empyema have been reported, usually in patients with underlying pulmonary disease. In a series of 28 cases of bronchiectasis in which the organism was recovered, it usually appeared as a secondary invader. It seems to have low pathogenicity in the respiratory tract until some other infection or physiologic disturbance decreases the natural resistance of the host, which enables active infection, most commonly liver disease such as cirrhosis, to occur.

Pasteurella infection also may be septicemic or occur with meningitis. The pathology and pathogenesis are similar to those of other organisms.

CLINICAL MANIFESTATIONS

In cases of local infection from a scratch or bite, the usual clinical pattern shows swelling, erythema, and tenderness within a few hours of the bite; most symptoms occur within the first 24 hours. A gray serous or sanguinopurulent discharge from the puncture sites may be present. Signs of systemic toxic effects, such as chills and fever, may or may not be present; regional lymphadenopathy often is evident. Less commonly, the infection may be lower grade and smoldering.[37] As noted, osteomyelitis and tenosynovitis most often occur after cat bites because of the sharpness of cats' teeth.

Lee and Buhr[26] found *P. multocida* to be the most common infecting organism in a report of 69 dog bites that had been cultured; 20 of the bites became grossly infected, and *P. multocida* was isolated from 10. Of 30 wounds that were sutured, 14 (47%) were infected with *P. multocida*. Other unusual localized infections include chronic skin ulcers, secondary infection of a gouty joint, and infection of a compound fracture site and an amputation site.[48] Preexisting joint disease seems to be a risk.

Clinical manifestations of patients having respiratory complaints are not unusual. Most of the isolates have been associated with chronic bronchitis, bronchiectasis, chronic sinusitis or otitis media, and pneumonia. Several cases of massive pulmonary abscesses, pleural effusion, and empyema also have been reported. Larsen and Holden[25] described a 14-year-old girl with chronic otitis media for 2 years who developed a *P. multocida* cerebellar abscess. A case of epiglottitis caused by this organism has been reported in an adult.[23] A child developed Ludwig angina after having a nonbite exposure. A 15-year-old boy with Kikuchi disease and *P. multocida* bacteremia has been described.[54]

In a report of 136 cases of *P. multocida* infection that were not related to animal bites, the most common site of infection after the respiratory tract was the abdomen; the organism was recovered from 10 patients with appendicitis. Eight isolates were from the female reproductive tract, four from the urine, and one from a chronic sacral abscess.[21] Whether these cases are secondary to ingestion of the organism or to hematogenous spread has not been determined. Raffi and colleagues[36] described three children with appendiceal peritonitis associated with *P. multocida*. The organism also has been seen in cases of peritoneal dialysis–associated peritonitis secondary to puncture of dialysis tubing.[27,28]

The disseminated infections are the other major clinical group of *Pasteurella* infections. Isolated bacteremia may be present[35]; however, most of these cases have been meningitis, many of which were mistaken for *Haemophilus influenzae* or *Neisseria meningitidis* infection because of the morphologic similarities among these organisms. In a review of the subject in 1967, Controni and Jones[7] noted 14 confirmed cases of *Pasteurella* meningitis; 11 occurred in adults, and 3 occurred in children. Eight of the 14 patients had a history of accidental or surgical trauma. The mortality rate was 50 percent, but only five patients were treated with antibiotics. Evaluation of the cerebrospinal fluid showed white blood cell counts ranging from 580/mm^3 to 5200/mm^3, all with a predominance of polymorphonuclear leukocytes. More recently, Green and coworkers[15] reviewed 29 cases of *P. multocida* meningitis in adults.

The first reported neonate with *Pasteurella* meningitis died at 88 hours of age.[1] The mother had a fever in the postpartum period, but her pretreatment cultures were lost, so verification of the source was impossible.[7] Since then, a case of *Pasteurella* chorioamnionitis associated with premature delivery and neonatal sepsis and death within 1.5 hours of delivery has been reported.[44] Gingival cultures of a pet cat that had scratched a mother numerous times during pregnancy also yielded *P. multocida*. Subsequently, several young infants with septicemia and meningitis caused by this organism survived without apparent sequelae after treatment with penicillin or ampicillin and gentamicin.* Pizey[34] reported another case of neonatal infection in a 3-week-old infant with septic arthritis. *P. multocida* infection may take a rapidly fatal course even in an older infant.[41,46] Clapp and associates[6] described two infants whose disease was associated with nontraumatic facial licking by pets, an avoidable exposure. In another report, a case of in utero infection at 12 weeks' gestation was described.[50] A neonate with meningitis and cervical spine osteomyelitis with full recovery has been reported.[18,19] Other neonatal infections, primarily sepsis and meningitis, have been described with similar incidental exposure, usually licking by a pet.

*References 2, 10, 14, 24, 38, 47.

DIAGNOSIS AND TREATMENT

Although *P. multocida* is one of the more likely pathogens to cause infection of cat or dog bites, its clinical manifestations are not unusual. Diagnosis of *P. multocida* infection can be made definitively only by culture. It may resemble several other organisms morphologically, but identification should not be difficult to make. The fact that it does not require X and V factors for growth should distinguish it from *H. influenzae*. Its production of indole should differentiate it from the *Neisseria* group, and its inability to grow on MacConkey agar or a bile salt medium should distinguish it from *Acinetobacter* spp. and the enteric organisms.

The drug of choice for *P. multocida* infection is penicillin, to which the organism is exquisitely sensitive. This feature may be used as a rapid means of distinguishing it from *H. influenzae* or the Enterobacteriaceae. Rare strains producing β-lactamase and resistance to penicillins have been recovered.[39] The organism usually is sensitive to a wide variety of other antibiotics, including ampicillin, other broad-spectrum penicillins (e.g., ticarcillin, piperacillin, mezlocillin), amoxicillin/clavulanic acid,[12] tetracyclines, parenteral cephalosporins (particularly second-generation and third-generation agents),[32] cefuroxime, cefpodoxime, and chloramphenicol. Semisynthetic penicillins (e.g., nafcillin, dicloxacillin), erythromycin, some orally administered cephalosporins (cephalexin, cefaclor), clindamycin, and aminoglycosides have relatively low activity against *P. multocida*.[8,13,43] Azithromycin seems to have acceptable activity,[6] as does ciprofloxacin.[22] Trimethoprim-sulfamethoxazole may be an alternative, particularly for patients unable to take a β-lactam antibiotic.[40] Surgical drainage or débridement also may be necessary. The duration of treatment depends on the primary disease process. Seven to 10 days generally is adequate for local infections.

PROGNOSIS AND PREVENTION

Proper cleansing and débridement of wounds caused by animal bites or scratches is important in prevention of *P. multocida* infection. Lee and Buhr[26] found that suturing wounds caused by a dog bite was associated with a higher incidence of infection. Whether a wound is sutured often depends on the site and the potential cosmetic result. The use of prophylactic antibiotics to prevent infection after animal bites is controversial. Some experts recommend their use for facial bites, if a delay occurs in seeking medical assistance, for cat bites, or for patients with immunocompromising conditions.

Limiting contact with wild and domestic animals that may harbor the organism probably is the only definitive way to prevent infection. Teaching proper handling of pets and keeping pets from licking infants and young children, particularly on the face, may help. No vaccine for human use is available.

Prognosis depends on the particular site of infection. With appropriate treatment, resolution usually occurs, but the healing process may be very slow, particularly in local infections with extension to the bone or tendons.[9,49]

disproportionately affects low-income countries.[86] Epidemic, endemic, and a mixture of the two forms occur. Epidemic cholera typically occurs in populations with little preexisting immunity and affects both children and adults. Endemic cholera tends to affect children with a higher incidence and severity because of lower levels of acquired immunity relative to that in adults.[21]

The incidence of cholera has increased since 2000.[98] In 2010, nearly 50 countries, mostly in Sub-Saharan Africa and Asia, reported 317,534 cases, 7543 deaths, and a case-fatality rate of 2.4 percent.[98] The United States reported 15 cases in 2010, all imported.[98] The disease burden of cholera is considered vastly underreported, and the actual number of cases is estimated at 3 to 5 million annually, with more than 100,000 deaths.[94] Recent outbreaks occurred in the Democratic Republic of Congo, the Republic of Congo, Cameroon, Chad, Niger, Iraq, Nigeria, Sudan, Somalia, Angola, Zimbabwe, and Haiti.[95] In 2011, Haiti reported over 500,000 cholera cases and 7000 deaths shortly after the October 2010 outbreak,[70] likely from a South Asian variant.[17] The case fatality rate during the recent Haitian outbreak began at 7 percent, one of the highest recorded rates in recent history, and then fell to 1.3 percent, just slightly above the generally accepted benchmark of 1 percent.[23] Many organizations advocate for an integrated and comprehensive approach to the control and prevention of this global public health problem.

HISTORY

Cholera has long been indigenous to the Ganges River valley in northern India; however, the modern history of cholera is described in seven discrete pandemics, all originating from Asia and all presumably caused by the O1 serogroup.[6] The first six pandemics, caused by the classic biotype, occurred between 1817 and 1923. The ongoing seventh pandemic began in Indonesia and South East Asia in 1961, and then spread throughout Asia and Africa. By 1991, it appeared in Peru and spread throughout Latin America. This most recent pandemic was caused by the El Tor biotype, which has almost completely replaced the classic biotype and is the longest and most widespread of all pandemics to date.[6] Several atypical El Tor variants containing phenotypic and genetic characteristics of the classic biotype were recently recognized, suggesting the emergence of hybrids.[78] In 1992, the first non-O1 serogroup isolated in association with an epidemic was reported.[77] This new O139 Bengal serogroup emerged in India and Bangladesh, raising concern for an eighth pandemic, but has not spread beyond the region to date.

The disastrous saga of cholera over the past 2 centuries helped shape public health as a discipline. Beginning in 1826, during the second cholera pandemic, many jurisdictions were induced to establish local sanitation and health boards, eventually evolving into the first organized public health apparatus. During the London cholera epidemic of 1854, investigations by Dr. John Snow demonstrated that transmission of the disease was associated with consumption of contaminated drinking water from the city's infamous Broad Street pump; this episode is considered the first scientific public health investigation and gave rise to modern epidemiology.[29] In 1866, an epidemic in New York City led to the creation of the first Board of Health in the United States, and cholera became the first reportable disease.

The Italian scientist Fillipo Pacini identified the comma-shaped organism in 1854, but this discovery was overlooked until Robert Koch identified the cholera bacillus in 1883 during the fifth pandemic. Koch's cholera discoveries contributed to his pioneering work that began the field of Medical Microbiology.[29] The addition of glucose to enhance the absorption of sodium in oral rehydration therapy, the cornerstone of cholera treatment, has saved the lives of millions and is heralded as one of the most important medical advancements of the 20th century.[29]

MICROBIOLOGY

V. cholerae is a curved gram-negative rod classified by biochemical tests and subdivided into serogroups based on the somatic O antigen. It belongs to the family Vibrionaceae, which differs from the related family Enterobacteriaceae in being oxidase-positive and motile with a single flagellum. Vibrios are fermentative and oxidative in metabolism. They have few nutritional requirements and can grow in glucose as the sole source of carbon and energy. Most vibrios are marine organisms, and most grow best in 2 to 3 percent sodium chloride under aerobic conditions. Although neither the typical comma shape of *V. cholerae* nor its motility is seen on Gram stain, both are apparent in wet mount even on fresh fecal samples. If motility stops after adding anti-*Vibrio* antiserum, this establishes a presumptive diagnosis of the homologous organism.

Numerous *Vibrio* spp. exist, most of which are nonpathogenic in humans. *V. cholerae* spp. includes more than 200 serogroups classified according to the antigenic characteristics of the lipopolysaccharide O antigen.[9] To date, only *V. cholerae* organisms carrying the somatic O antigens O1 and O139 are associated with epidemic disease. Some non-O1 *V. cholerae* serogroups cause sporadic diarrheal illness, which can be severe and sometimes invasive and inflammatory.

The O1 serogroup is divided further into two biotypes, classic and El Tor, based on biochemical properties and phage susceptibilities. The classic biotype traditionally causes a more severe disease, but the El Tor biotype may be better adapted to persist in the environment and establish epidemics. The classical biotype expresses genes conferring human virulence more than the El Tor biotype, which shows enhanced expression of genes for biofilm formation, chemotaxis, and transport of amino acids, peptides, and iron.[9] Classic and El Tor biotypes are divided into three serotypes (i.e., Ogawa, Inaba, and Hikojima) based on their dominant heat-stable lipopolysaccharide somatic antigens. The O139 serogroup comprises several genetically diverse strains, including nontoxigenic variants, and is genetically related to the O1 El Tor biotype.[27] Media used to isolate cholera organisms

in stool include thiosulfate citrate bile salts sucrose (TCBS) agar and tellurite taurocholate gelatin agar. The appearance of yellow ("popcorn") colonies on TCBS agar is considered highly suggestive of *V. cholerae*. The bacterium is confirmed further by its ability to grow in the presence (or absence) of salt and by serology.

PATHOGENESIS

The pathogenic paradigm of *V. cholerae* comprises colonization of the small bowel mucosa followed by release of one or more enterotoxins, the most potent of which is the oligomeric cholera toxin itself. *V. cholerae* attaches to the intestinal mucosa by virtue of proteinaceous hairlike fimbriae, the most important being the toxin-coregulated pilus.[77] These pili mediate microcolony formation of the intestinal epithelium. Colonization is facilitated by a protease that degrades mucin[82] and epithelial tight junction–associated proteins and a single flagellum, which accelerates approach to the intestinal mucosa in conjunction with chemotactic receptors and intracellular sensor molecules.[13]

V. cholerae organisms shed in the stool of an infected individual act more virulently than strains acquired from an environmental source. Serial passage through multiple patients may augment virulence further, partly accounting for the violent epidemics occurring throughout history.[57] On intestinal passage, genes required for acquiring nutrients and motility are upregulated, whereas genes required for chemotaxis are downregulated. This increased virulence was confirmed in an animal model in which *V. cholerae* shed by mice has a 10-fold lower infectious dose than organisms grown in vitro.[57] Reduced chemotaxis prevents dispersion in environmental waters and increases clumping of the bacteria[14]; the resulting increased concentration of organisms also may contribute to the vigor of cholera outbreaks.

Cholera toxin is composed of five identical binding (B) subunits and one active (A) subunit. Similar in structure and function to the heat-labile toxin produced by enterotoxigenic *Escherichia coli*,[62] cholera toxin binds to the GM_1 ganglioside receptor on the surface of intestinal epithelial cells. The A subunit is internalized into the cell, where it activates adenylate cyclase by ADP-ribosylation of the $G_{s\alpha}$ protein. This results in upregulation of cyclic adenosine monophosphate, causing an increase in chloride secretion from the intestinal crypt cells via the cystic fibrosis transmembrane conductance regulator chloride channel and a decrease in sodium chloride absorption by the villous cells. In addition to this mechanism, cholera toxin may have effects on prostaglandins and the enteric nervous system that could contribute to the voluminous diarrhea characteristic of the disease.[47] Water follows the loss of electrolytes along the osmotic gradient into the intestinal lumen. The dramatic loss of fluid and electrolytes rapidly leads to decreased intravascular volume and the complications of hypovolemic shock and metabolic acidosis. Although cholera toxin is responsible for much of the pathogenicity associated with the organism, strains mutated in cholera toxin still elicit mild diarrhea.[47] Several other toxins have been identified, but their exact role in pathogenesis and immune modulation is not completely understood. These include the zonula occludens toxin, which increases small intestinal mucosa permeability through the modulation of internal tight junctions, and the accessory cholera enteroxin, an integral membrane protein thought to function as an ion-permeable pore.[16,28,90] The multifunctional cholera toxin protein is also a powerful immunomodulator and may have potential applications in immunotherapeutics and as a mucosal or possibly epicutaneous adjuvant.[10,68]

The genetics of *V. cholerae* provide insight into the organism's pathogenicity and spread. The genome of 4 million DNA base pairs comprises two circular chromosomes,[22,40] the larger of which contains genes for growth and pathogenicity and the smaller contains elements of metabolism and regulation. The genes required for virulence can propagate laterally and among different strains. Required for pathogenicity are the cholera toxin genetic element and the *Vibrio* pathogenicity island, which encodes toxin-coregulated pilus and the critical regulator ToxT, the primary direct transcriptional activator of the virulence genes. The pathogenicity island can be moved between strains by phage transduction and chitin-induced transformation. Toxigenic strains emerge through the acquisition of the bacteriophage CTXΦ, which harbors the *ctxAB* gene encoding cholera toxin.[56] The complex regulatory system controlling expression of virulence genes includes the ToxT/ToxR regulator proteins, quorum sensing, and small RNA molecule, and differs among in vivo and in vitro life stages[12,42,56] and between clinical and environmental isolates.[59]

EPIDEMIOLOGY

Cholera is classically described as a waterborne illness, but it can also be transmitted via contaminated food. The incubation period depends on the inoculum, with lower inocula corresponding to a longer incubation period and decreased stool volumes.[47] Incubation generally is 1 to 3 days, with a range of several hours to 5 days. Symptoms usually last 2 to 3 days, and patients treated with antibiotics may be infectious for several days. Patients who are untreated remain infectious for 1 to 2 weeks. Although waterborne transmission is typical in developing countries of Asia and Africa, *V. cholerae* found in marine environments can be transmitted via undercooked shellfish.[20] The role of household animals in transmission is probably minimal,[81] and person-to-person transmission is rare, owing to the high infectious dose.[63]

Seasonal patterns in endemic areas have long been recognized for cholera outbreaks, with a predilection for warmer months. Studies conducted during interepidemic periods suggest a complex interaction between humans and the environment. *V. cholerae* exists in saline aquatic environments in a viable but nonculturable state, mostly in the form of metabolically dormant biofilm associated with zooplankton.[44,87] This latent form originates from human stool, survives gastric acidity, and causes infection. When human cases begin to occur in a community, direct contamination of food and water may occur, circumventing the need for the aquatic reservoir.[24] Seasonal

epidemics are associated with other factors that affect the environmental reservoir, including changes in zooplankton blooms, the abundance of chitin, and rainfall. Several cholera prediction models have been developed based on these factors.[45,73,74] Recent evidence suggests that increases in vibrio-infecting bacteriophages may be associated with the end of an outbreak and interepidemic periods in Bangladesh.[25,26]

Host factors associated with susceptibility to *V. cholerae* include age, immunity, blood type, and reduced gastric acid production. Age groups commonly affected by cholera typically include young children because susceptibility depends on preexisting immunity. In endemic areas such as Bangladesh, cases of cholera are concentrated in the 2- to 9-year-old age category, followed by women of childbearing age.[47] The increased susceptibility of children is further supported by a more recent prospective study in Kolkata, India, where the burden of cholera was greatest in children younger than 2 years old and cases were more likely where a household member had diarrhea.[37,83] Mucosal humoral immune responses in both children and adults to *V. cholerae* may be decreased with intestinal helminth coinfection.[37] Breast-feeding protects against disease in children colonized with *V. cholerae*.[31] Acholorhydric patients are at higher risk for acquiring infection, because bacteria are more likely to survive the gastric environment and colonize the small intestine.[65] Observations of increased cholera severity among people with blood type O were confirmed through challenge and cohort studies,[36,52] presumably because of binding of blood type O antigen to cholera toxin.[39] For reasons that are not completely understood, individuals with the Lewis blood group Le(a+b–) phenotype may also be at increased risk for symptomatic disease in contrast to those with Le(a–b+) and Le(a–b–).[4] Other host genetic factors likely also play a role, as evidenced by familial clustering of cases and gene association studies.[33,51,71]

CLINICAL MANIFESTATIONS

Most individuals infected with *V. cholerae* have only mild symptoms, indistinguishable from symptoms caused by other enteric infections. Individuals who develop disease urgently need fluid resuscitation and replacement of ongoing losses. Of all causes of infectious diarrhea, the stool volumes passed and the rapidity by which dehydration develops are greatest with cholera.[80] In severe disease, stool volume can exceed 250 mL/kg body weight in a 24-hour period.[60,72]

The most distinctive clinical feature of cholera is the painless passage of voluminous, watery stools. Termed "rice water stools" because of the watery, colorless diarrhea dotted with mucus, cholera stools may have a fishy smell or may be nearly odorless. Other common symptoms include abdominal cramping and vomiting. Abdominal cramping is probably due to increased abdominal secretions and resulting small bowel distention. Vomiting commonly occurs a few hours after the onset of diarrhea, but it also occurs later in the course of the illness.[15,38,64]

Complications of cholera relate mostly to the massive loss of intravascular volume and electrolytes. If cholera is not treated promptly, diarrhea and vomiting eventually lead to dehydration, which is most often isotonic. Patients with severe cholera may experience vascular collapse, shock, and death rates of 50 percent, starting within hours after the onset of diarrhea.[77] Related to the massive loss of intravascular volume and hypoperfusion, bicarbonate losses in stool and hyperphosphatemia, acidosis also may develop.[91,93] Compensatory tachypnea may be seen in patients with acidosis. In addition to bicarbonate losses in stool, potassium is also lost and may not be reflected in serum potassium levels; acidosis induces the shift of intracellular potassium into the intravascular space in exchange for hydrogen ions, resulting in decreased total body potassium and potentially normal serum potassium values. As the acidosis is corrected, serum hypokalemia may result. In cases complicated by severe malnutrition, in which body potassium stores already are depleted, hypokalemia may be quite severe and manifest as paralytic ileus. This hypokalemia is rarely associated with severe cardiac arrhythmias, but it may manifest as changes on electrocardiogram.

After dehydration, hypoglycemia is the second most common cause of death in pediatric patients with cholera.[8] In one study, the mortality rate in pediatric patients with hypoglycemia caused by cholera was 15 percent in contrast to 1 percent mortality in patients with normoglycemia.[8] Although the precise mechanism of hypoglycemia is unknown, malnourished children who are acutely ill have lower glycogen stores and impaired gluconeogenesis. Special attention should be given to monitor patients with concomitant malnutrition and cholera for hypoglycemia.

Severe cholera is diagnosed in individuals who present with clinical signs and symptoms of severe dehydration (loss of ≥15% of total body water or loss of ~10% of body weight). Common signs of severe volume depletion include a combination of decreased skin turgor, depressed anterior fontanelle in infants, lack of tears and sunken eyes, dry mouth, anuria, tachycardia, decreased peripheral perfusion, and hypotension (Fig. 117-1). In some cases, mental status changes may be a sign of volume

FIGURE 117-1 ■ An adolescent girl with severe dehydration from cholera. Characteristic features include obtundation, sunken eyes, and "tenting" of the abdominal skin and subcutaneous tissues after firmly pinching the abdomen.

depletion, but more common are somnolence, restlessness, and lethargy.

LABORATORY FINDINGS AND DIAGNOSIS

Laboratory abnormalities in patients with cholera relate to the massive loss of volume and electrolytes. The hypovolemic state can lead to hemoconcentration, causing increased hematocrit, serum specific gravity, serum protein, serum creatinine, and blood urea nitrogen.[91,93] Because of the loss of sodium that accompanies water loss, serum sodium is either slightly low or normal.[47,72] As noted earlier, although potassium loss occurs in the stool, serum potassium may be normal, whereas total body potassium may be decreased. Acidosis caused by loss of bicarbonate in stool and lactic acidosis can result in a serum bicarbonate concentration of less than 15 mmol/L.[91,93] Serum creatinine and blood urea nitrogen also are elevated as a result of a decreased glomerular filtration rate. The common abnormalities of sodium, potassium, bicarbonate, and glucose mandate early determination of serum glucose and electrolytes as a guide to therapy.

Although presumptive diagnosis is made on the basis of typical oxidase-positive colonies from stool samples that agglutinate with O1 or O139 antiserum, conventional culture methods remain the gold standard. The characteristically motile organisms can be visualized directly using darkfield microscopy,[7] but few laboratories except those in cholera-endemic regions are experienced with this technique. If cholera is suspected, special culture media, such as TCBS agar, should be used to culture the organism.

In epidemic settings or in areas of intense transmission, a rapid vibrio dipstick test may be used. This is a one-step immunochromatographic test developed by the Institut Pasteur for rapid detection of cholera O1 and O139 from stool samples. The method has been tested in Madagascar, Bangladesh, and Mozambique, where the specificity ranged from 84 to 100 percent and sensitivity ranged from 94 to 100 percent.[66,92] It is especially advantageous because it requires minimal technical skill, can be read in 10 minutes,[66] and detects cholera from rectal swabs.[11,92] Confirmation of *V. cholerae* in stool also can be done using polymerase chain reaction amplification or oligoprobes.[43,58,89]

TREATMENT

The cornerstone of cholera management is fluid resuscitation. When fluid resuscitation is initiated, previous losses must be estimated based on the degree of dehydration and replaced and ongoing losses must be quantified and replenished. Replacement fluids in children with cholera should be similar to fluids that are lost, such as lactated Ringer solution (Table 117-1).[41,96] The ideal solution contains amounts of bicarbonate and potassium sufficient to replace what is lost in stool.

TABLE 117-1 **Electrolyte Concentration in Cholera Stool and in Fluids Used for Rehydration and Replacement of Stool Losses**

	Electrolyte Concentration (mmol/L)				
	Na^+	Cl^-	K^+	HCO_3^-	Osmolality
Cholera Stool					
Adults	130	100	20	44	300*
Infants and children	100	90	33	30	300*
Hydration Solutions					
WHO oral rehydration	75	65	20	10†	170‡
Intravenous					
Dhaka	133	98	13	48	273
Lactated	130	109	4	28§	251
Ringer					
5:4:1	129	97	11	44	281

*Osmolality includes unmeasured osmotically active molecules (primarily organic acids) in addition to electrolytes.
†As citrate.
‡From electrolytes only; also contains 75 mmol/L of glucose.
§As lactate.
WHO, World Health Organization.

At the International Centre for Diarrhoeal Disease Research, Bangladesh, where thousands of cholera patients are treated annually, patients of all ages are seen with severe dehydration of rapid onset. Many arrive for treatment in hypovolemic shock. The extent of dehydration is determined, one or two intravenous catheters are inserted, and isotonic resuscitation solution is administered rapidly. The composition of the preferred solution at the Center (Dhaka solution) is listed in Table 117-1. The solution contains Na^+, Cl^-, K^+, and HCO_3^-, but no glucose. The complete estimated deficit is administered over 4 hours, whereupon ongoing losses and maintenance fluids are provided. Serum glucose and electrolytes are determined rapidly, with administration of glucose as needed based on these results. Because severely dehydrated patients characteristically are anuric, concern may exist over early administration of potassium. The rapid onset of dehydration in cholera patients reduces this risk, however, and acute tubular necrosis rarely is seen.[72,93] A greater concern may be the rapid shift of potassium from the circulation on correction of acidosis. Patients treated in this manner respond dramatically. After the 4-hour resuscitation phase, most patients can begin to accept oral rehydration solution. Close attention to fluids and electrolytes is required for the duration of the diarrhea.

Although oral and intravenous rehydration methods are acceptable in theory for the management of cholera, the severity of losses in severe cholera renders intravenous rehydration the mainstay for treatment initiation

FIGURE 117-2 ■ A cholera cot: A simple folding cot covered with plastic that has a hole and bucket for collecting the stool output, as used for the care of cholera patients at the International Centre for Diarrhoeal Disease Research, Bangladesh. The bucket is calibrated, and the volume of stool (and replacement fluids required) can be calculated easily. The plastic sheet is cleaned daily and between patients.

in these cases. Not only do intravenous fluids allow predictable and rapid expansion of intravascular fluid volume to occur, they also ensure timely replacement of ongoing losses that may be challenging because of excessive purging.[69] Because massive volumes of fluid are lost in severe cholera, the volume deficit is frequently underestimated and rehydration therapy is often inadequate. Treatment of severe cases is best carried out by those with adequate training and experience in the management of these cases. Mild cases can be managed with oral rehydration solution (see later discussion). Guidelines for the initial management of cholera in an outbreak setting have been published by the World Health Organization (WHO) Global Task Force on Cholera Control.[97]

The use of a "cholera cot" is extremely helpful in quantifying ongoing fluid loss and for patient comfort (Fig. 117-2) and can easily be set up in cholera treatment centers. It is constructed of a simple cot with a hole in the center through which a plastic sheet drains into a graduated bucket below via a funnel. This allows for accurate quantification of ongoing losses and permits the patient to remain horizontal, an important advantage if the patient is initially hypotensive. Attention given to tachycardia and signs of hypoperfusion in prostrate patients is essential.

The WHO-approved oral rehydration salts (see Table 117-1) are recommended for patients with no detectable dehydration or mild dehydration, provided that the patient can drink sufficient quantities to replace the deficit and keep pace with ongoing losses. Oral rehydration solution can also be used for patients with severe dehydration to replace ongoing losses after initial intravenous replacement therapy. For cholera, oral rehydration solution that is made with rice rather than with glucose is preferred, because carbohydrate reduces the purging rate.[34,61,99] Food should be offered to patients as soon as they are able to eat and should not be restricted. Supplementation with zinc reduces the duration of diarrhea and the volume of stool output in children with cholera.[76] Effective use of oral rehydration solution requires extra effort in treating pediatric patients with cholera. Parents need instruction to encourage and supervise oral rehydration solution intake by the child, including taking small amounts frequently. Parents also need reassurance that oral rehydration is still effective despite occasional vomiting.

A short course of antibiotics should be given to children with clinically significant cholera. This approach reduces the amount of diarrhea, the duration of illness, and the infectious dose in stools.[32,77] Antibiotic therapy may also favorably affect the dynamics of transmission and hence have public health implications.[67] Because of high resistance rates in some areas, the organism should be isolated and tested for susceptibility using standard methods for gram-negative enteric bacteria. On average, patients not treated with antibiotics may continue to shed organisms for 5 or more days.[53]

Treatment options for cholera in pediatric patients are listed in Table 117-2. First-line therapies for *V. cholerae* in children include single-dose azithromycin or erythromycin for 3 days in younger children, and a single dose of doxycycline may be given to children older than 8 years. Tetracycline and doxycycline are generally not recommended in children younger than 8 years because of the risk for dental staining. In addition, ciprofloxacin is also effective against susceptible strains.[67] Trimethoprim-sulfamethoxazole has demonstrated efficacy in children,[46] although resistance may be present among O139 strains.[1] Both single-dose azithromycin 20 mg/kg and single dose ciprofloxacin 20 mg/kg achieved clinical success rates similar to a those of a 12-dose course of erythromycin in children 15 years of age or younger, but ciprofloxacin was less effective in eradicating *V. cholerae* from the stool.[49,79] Recently, single-dose azithromycin showed superiority to single-dose ciprofloxacin in children.[48]

Multidrug-resistant strains of *V. cholerae* have been isolated from both clinical and environmental settings, and the number of pathogenic strains resistant to one or more antibiotics is increasing.[50] Several different mechanisms of drug resistance have been reported and include the production of extended-spectrum β-lactamases, enhanced multidrug efflux pump activity, plasmid-mediated quinolone and fluoroquinolone resistance and chromosomal mutations.[5,30,35,88] The horizontal transfer of resistance determinants with mobile genetic elements such as integrons and the integrating conjugative elements assist in the dissemination of drug resistance.[30] SXT, first identified in a *V. cholerae* O139 strain from India, is an integrating conjugative element carrying a resistance gene for trimethoprim-sulfamethoxazole, streptomycin, and chloramphenicol.[30] Appropriate antibiotics, usually prescribed before obtaining sensitivity testing results, should be administered according to local resistance patterns and should be monitored for changes in sensitivity.

TABLE 117-2 **Antimicrobial Therapy of Cholera***

Agent	Single Dose	Multiple Dose
Azithromycin	20 mg/kg; maximal dose 1 g	
Erythromycin	Not evaluated	50 mg/kg/day erythromycin divided into four doses for 3 days; maximal dose 2 g/day
Doxycycline	2-4 mg/kg; maximal dose 300 mg	
Tetracycline	Not evaluated	50 mg/kg/day divided into four doses for 3 days; maximal dose 2 g/day
Ciprofloxacin‡	20 mg/kg; maximal dose 1 g	30 mg/kg/day divided into 2 doses for 3 days; maximal dose 1 g/day
Trimethoprim-sulfamethoxazole	Not evaluated	10 mg trimethoprim/50 mg sulfamethoxazole/kg/day divided into 2 doses for 5 days; maximal doses 320 mg trimethoprim and 1.6 g sulfamethoxazole daily
Ampicillin	Not evaluated	50 mg/kg/day divided into four doses for 3 days; maximal dose 2 g/day
Furazolidone	7 mg/kg; maximal dose 300 mg†	5 mg/kg/day divided into four doses for 3 days; maximal dose 400 mg/day

*Antimicrobial therapy is an adjunct to fluid therapy for cholera and is not an essential component. It reduces diarrhea volume and duration, however, by approximately 50 percent. The choice of antimicrobial agent is determined by the susceptibility pattern of local strains of *Vibrio cholerae* O1 or O139. Resistance to all agents has been reported and is common in some areas.
†Single-dose therapy with these drugs has not been evaluated systematically in children, and recommendations are extrapolated from experience in adults.
‡The fluoroquinolones, such as ciprofloxacin, are only approved for use in children <18 years old in the United States for special indications because of concerns about arthropathy; multi-dose therapy has not been evaluated systematically in children, and recommendations are extrapolated from experience in adults.

PREVENTION

Because contaminated food and water are the main routes of transmission of pathogenic *V. cholerae*, strategies to improve access to safe water sources and a clean food supply are the best methods for prevention. Proper sanitation methods also play a key role. During outbreaks, measures to increase awareness of cholera transmission and means to decrease spread should be communicated to the public. These measures include proper hand washing (especially after defecating), proper cooking of food, and identifying ill individuals so they can be treated.

Vaccination is another method of preventing cholera. Whole-cell, inactivated parenteral vaccines have been superseded by inactivated oral vaccines and are currently the only cholera vaccines commercially available and are used mostly as travel vaccines. The whole-cell plus B subunit vaccine (WC-rBS; Dukoral) consists of approximately 1×10^{11} inactivated whole cells of the classic and El Tor biotypes of *V. cholerae* O1, serotypes Inaba and Ogawa with 1 mg of recombinant cholera toxin B subunit. The vaccine is prequalified by the WHO and approved for children older than 24 months of age. It is supplied as 3-mL single-dose vials, each provided with a sachet of sodium bicarbonate buffer. The buffer solution is prepared by dissolving the sachet in 150 mL of water immediately before consumption. The vaccine must be refrigerated during shipping. Two doses administered at least 15 days apart are recommended for adults and three doses for children younger than 5 years of age. A large field trial in Matlab, Bangladesh showed protective efficacy of approximately 85 percent during the first 6 months after vaccination among women and children over the age of 2 years,[18] but this protection was not sustained in children younger than 5 years.[19] In Beira, Mozambique, one or more doses of WC-rBS vaccine during a mass campaign protected nearly 80 percent of children and adults against culture-confirmed cholera in a setting where the human immunodeficiency virus seroprevalence rate is 20 to 30 percent.[54] All confirmed cases were due to an O1 El Tor Ogawa variant strain expressing the classic cholera toxin, indicating that the vaccine also provided protection against these newer strains of cholera.[21] The WC-rBS vaccine also may provide herd immunity in endemic settings.[2]

Two closely related oral vaccines are also available (mORCVAX and Shanchol). These killed bivalent (O1 and O139) vaccines do not contain the B subunit, do not require an oral buffer, and appear safe and immunogenic in trials conducted in both Vietnam and India.[3,55] Protective efficacy after two doses was about 60 percent and remained near 50 percent 3 to 5 years after vaccination.[84] The Vietnamese vaccine (mORCVAX) is licensed and used nationally. The Indian vaccine (Shanchol) is prequalified by the WHO and licensed for use in adults and children older than 1 year of age. Two doses are administered in a 2-week interval, with a booster dose recommended 2 years after primary vaccination.[21]

The live, attenuated cholera vaccine, CVD 103-HgR, is genetically engineered from an O1 classic Inaba strain by deletion of the *ctxA* subunit and insertion of a marker

mercury ion receptor gene into the chromosomal *hlyA* locus. Protection of 100 percent was seen against the homologous strain in challenge studies of North American volunteers and lasts at least 6 months.[85] It was previously licensed in the 1990s, but subsequently did not demonstrate protection in children or adults living in an endemic area,[75] potentially as a result of both direct and indirect protection.[2] In an outbreak setting, however, a single dose provided 79 percent protection.[14] Although CVD 103-HgR is not currently available, the U.S. Food and Drug Administration accepted an investigational new drug application to begin additional clinical trials in North America. Several other candidate oral cholera vaccines, mostly live, attenuated, are under development, including Peru-15, a genetically engineered strain derived from an O1 El Tor Inaba strain.[21]

Cholera vaccines should be used in conjunction with other prevention and control strategies in areas where the disease is endemic and considered in areas at risk for outbreaks.[98] The impact of reactive vaccination in response to outbreaks is less clear, although recent mathematical models predict a substantial benefit with prompt institution.[21]

CHAPTER 118

Vibrio parahaemolyticus

David Y. Hyun

Vibrio parahaemolyticus is recognized worldwide as a cause of foodborne disease associated with consumption of seafood, in particular crustaceans and mollusks, and occasionally as a cause of wound infections and sepsis in immunocompromised hosts. *V. parahaemolyticus* was isolated first in Japan during a foodborne outbreak in 1951. Almost 10 years after it was first described, the organism was classified correctly in the genus *Vibrio*,[9] and its distribution in coastal waters and estuaries of temperate climates around the world was recognized. The regional differences in the incidence of this disease are related to patterns of consumption of marine products and practices of food preparation. In Japan and Taiwan, where fish and shellfish are a major source of dietary protein and frequently consumed raw, *V. parahaemolyticus* accounts for 10 to 40 percent of foodborne outbreaks.[2,66] In the United States, the first confirmed foodborne outbreak occurred in Maryland in 1971, secondary to consumption of contaminated crabmeat.[22] Since then, sporadic outbreaks have been reported,[6,7,14,22,24] showing the potential risk for development of infectious and toxic syndromes from marine products in the United States.[29]

BACTERIOLOGY

V. parahaemolyticus is a gram-negative, non–spore-forming, curved rod with rounded ends that possess a polar flagellum.[54] On surfaces or in viscous environments, *V. parahaemolyticus* can differentiate into swarmer cells equipped with additional shorter lateral peritrichous flagella.[53] *V. parahaemolyticus* is a facultative anaerobe with respiratory and fermentative metabolisms. Similar to most vibrios, it is an oxidase-positive nonfermenter of lactose.[8] It is arginine dihydrolase–negative and ornithine decarboxylase–positive. The requirement of sodium and enhancement of growth in a specific range of concentration differentiate it from *Vibrio cholerae* and *Vibrio mimicus*. The optimal sodium concentration range is 2 to 4 percent; a concentration greater than 8 percent inhibits its growth.[82]

V. parahaemolyticus produces round, blue-green colonies on the widely used *Vibrio*-selective thiosulfate citrate bile salt sucrose (TCBS) agar. This medium inhibits most fecal flora by the presence of bile salts and a highly alkaline pH. Direct plating on TCBS agar may be used for feces and other clinical specimens, but food samples that are not heavily contaminated require enrichment either in alkaline peptone water supplemented with 3 percent sodium chloride or in a strongly selective medium, such as Glucose Salt Teepol Broth.[82] The optimal pH for growth is in the neutral range, but *V. parahaemolyticus* can survive in alkaline media. Optimal growth temperatures are between 35° and 39°C (95° to 102.2°F).[86] Growth is remarkable in conventional media and foodstuff, with generation times of only 8 minutes[43]; a significant number of organisms can be found after a short period of inappropriate storage. Growth is inhibited at temperatures of 44°C (111.2°F) or greater. The degree of inactivation is greater with increased temperatures; a million-fold decline occurs in viable bacteria in shrimp homogenate kept at 100°C (212°F) for only 1 minute.[80] In laboratory conditions with low temperature and nutrient supply, *V. parahaemolyticus* has been shown to enter a viable but nonculturable state, during which the organism no longer can be cultured on routine growth media, but its viability can be confirmed using direct microscopic assays.[31,42,84]

The genome of *V. parahaemolyticus* consists of two circular chromosomes. Genes for a type III secretion system (TTSS) were identified in a pathogenicity island on chromosome 2.[51] Two types of nonredundant TTSS have been identified.[63] TTSS, which is considered a central virulence factor in salmonellae and shigellae, possesses needle-like structures that facilitate direct injections of bacterial proteins into a target host cell and is related strongly to the pathogenicity of inflammatory diarrhea seen with *V. parahaemolyticus* infections. This finding suggests that the presence of TTSS in *V. parahaemolyticus* differentiates its pathogenicity from that of *V. cholerae*, which does not carry the genes.[51]

EPIDEMIOLOGY

In the United States, *V. parahaemolyticus* is found along the East, West, and Gulf coasts.[25,43] Water, sediments, suspended particulates, plankton, fish, and shellfish have been shown to harbor the organism.[5,56] The organisms are present in highest numbers in water at temperatures between 17° and 35°C (62.6° to 95°F) and containing 0.5 to 2.5 percent salinity.[41] Marked seasonal and geographic variations occur, with maximal mean concentrations occurring during late summer and spring along the Gulf Coast.[25] The seasonal distribution correlates with outbreaks, predominantly between June and October.[4]

Finfish and all types of shellfish products, including oysters, clams, crabs, and shrimp may be involved in the transmission of the infection (Table 118-1).[41] The risk for acquiring infection is higher with molluscan shellfish because of their ability to concentrate contaminants and bacteria by filter feeding.[5,31,86] In oysters, the density of

TABLE 118-1 **Selected Outbreaks of *Vibrio Parahaemolyticus* Infection**

Setting	Persons Ill/ Exposed	Symptoms (%)	Incubation	Resolution	Medical Attention/ Hospitalization (%/%)	Vehicle	Risk Factor

C, Cramps; *D,* diarrhea; *F,* fever; *HA,* headache; *N,* nausea; *V,* vomiting.

V. parahaemolyticus may be 100 times greater than in the surrounding water.[25] The levels of contamination of seafood generally are low in freshly collected oysters, with the highest mean density of only 160 bacteria/g found in the United States.[25] In Japan, higher counts (up to 10^3 to 10^4/g) have been reported in market shellfish.[18] The minimum infective dose is thought to be in the range of 10^5 to 10^7 organisms, based on volunteer feeding studies.[27] More recent outbreaks of illness caused by oysters that met bacteriologic safety standards have raised questions about current recommendations, however.[23]

During the period 1973 to 1987, only 23/1869 foodborne disease outbreaks with known bacterial etiology reported to the Centers for Disease Control and Prevention (CDC) were caused by *V. parahaemolyticus*.[6] In 18 of these outbreaks, a shellfish was recognized as the food vehicle. No fatal cases were reported. Contributing factors included inadequate cooking (92%), improper holding temperature (75%), and food acquired from an unsafe source (75%).[6,7] Most of the affected individuals were adults, and no patterns of unusual susceptibility by age group or gender were noted. No evidence of secondary spread was found among family members. Between 1988 and 1997, 345 sporadic cases were reported to the CDC. Most infections were related to eating raw oysters. Most of these infections (59%) were gastroenteritis.[24] In the early summer of 2006, outbreaks of *V. parahaemolyticus* associated with consumption of contaminated shellfish harvested from a common area were reported across states of New York, Oregon, and Washington. Seventy-eight percent of the isolates tested had a subtype of O4:K12.[16]

Until more recently, *V. parahaemolyticus* infections were causally associated with multiple serotypes and occurred as sporadic cases or localized outbreaks.[58] In 1996, a sudden increase in incidence was seen in India, and 50 to 80 percent of the cases were attributed to a single serotype, O3:K6.[64] Shortly thereafter, O3:K6 strains were isolated from clinical samples from other countries in Asia.[59] In 1998, two outbreaks of gastroenteritis in the United States were associated with O3:K6.[15,24] By 2005, this pandemic clone was found in patients from Europe, South America, and Africa,[3,35,52] and other clones that genetically diverged from O3:K6, such as O4:K68 and O1:KUT, were isolated from clinical cases.[21] Although rates may have stabilized in some regions during the late 2000s,[33] cases and outbreaks associated with these pandemic clones continue to be reported in high numbers globally.[65,83]

PATHOGENESIS

The ability of certain strains of *V. parahaemolyticus* to produce β-hemolysis on Wagatsuma agar, known as the Kanagawa phenomenon (KP), was first epidemiologically associated with human pathogenicity.[55] KP is observed in 88 to 96 percent of strains from clinical specimens and in 1 to 2 percent of strains from environmental sources.[27,43,78] Thermostable direct hemolysin (TDH) produces KP.[77] TDH has a molecular weight of 42,000, consisting of two subunits of 21,000,[56] and, in contrast to other hemolysins produced by *V. parahaemolyticus*, is not inactivated by heating at 100°C (212°F) for 10 minutes. It is a pore-forming toxin that causes hemolysis by binding to and disrupting erythrocyte membranes.[37] TDH also has been shown to have enterotoxic activities, such as causing accumulation of fluid in rabbit ileal loop assays, invading intestinal mucosa,[20,81] and increasing intracellular calcium concentrations that

trigger secretion of chloride by intestinal cells.[71,75,76] TDH is cytotoxic, lethal to small experimental animals, and cardiotoxic.[88]

Certain KP-negative isolates from outbreaks have been shown to produce TDH-related hemolysin (TRH).[39] Although TRH is heat-labile, it shares similarities with TDH, such as hemolysis, production of fluid accumulation in the rabbit ileal loop model, and induction of chloride secretion in human colonic epithelial cells.[38,69] Likewise, some variants closely related to the original TDH by molecular analysis (Vp TDH/I and Vp TDH/II) have been isolated from KP-negative strains.[57]

When the *tdh* and *trh* genes had been cloned and sequenced, researchers realized that certain strains possess the genetic material but are phenotypically incomplete. Strains with a typical hemolysin-positive phenotype carried two chromosome gene copies, whereas *tdh* gene–positive strains with weakly positive or negative hemolysin phenotype possessed only a single chromosome gene copy.[60] Fewer than 50 percent of *trh* gene–positive strains produce TRH when examined by enzyme-linked immunosorbent assay.[73] Low-level expression of the *tdh* genes may be the reason for the KP-negative phenotype.[61] The expression of the *tdh* genes is controlled by the Vp-toxRS operon. The basal production of mRNA and the degree of transcriptional activation seem to be related to differences in the nucleotide sequences and strength of the promoter region.[61]

Some studies suggest that virulence mechanisms in addition to TDH and TRH exist and that the mere presence of the *tdh* or *trh* genes does not reliably correlate with virulence of a given strain.[81,86] One study found that 5.6 percent of their clinical isolates were toxin negative by PCR.[50] *V. parahaemolyticus* requires intestinal colonization factors to cause disease. A variety of pili and other potential colonization factors are present, but the evidence is too poor to implicate any of the candidate adhesins in virulence.[18] Adherence of *V. parahaemolyticus* to intestinal epithelial cells of rabbits[19] and human small intestine[34,85] seems to require binding to complex carbohydrates or hemagglutinins of the host. Also, *V. parahaemolyticus* appears to disrupt epithelial barrier function, regardless of TDH and TRH production.[50]

The occurrence of cases with grossly bloody stools[14,40] is indirect evidence of either invasiveness or production of cytotoxin. Invasion of Caco-2 cells in culture has been shown in approximately 20 percent of strains.[1] KP-positive and KP-negative strains from clinical specimens can invade and colonize the mucosal cells of the rabbit ileum, producing acute inflammation, degeneration, and erosion of the villi.[8] Vibrios can be cultured from tissue specimens of spleen, liver, and heart in experimental animals, indicating spread through the lymphatic or circulatory systems.[11]

CLINICAL MANIFESTATIONS

The spectrum of intestinal disease varies from mild gastroenteritis to dysenteric syndrome. The incubation period typically is 15 to 24 hours (range, 4 to 96 hours)[4,74]; the variability presumably is related to the number of organisms ingested. Resolution is expected to occur in approximately 3 days,[56] but it varies from several hours to more than 10 days.[4,12] Fatigue may persist for a few days. Diarrhea (96%) and abdominal pain (95%) are the most frequent and earliest symptoms, accompanied by nausea, vomiting, and headache in 40 to 70 percent of cases. Chills and moderate fever are less frequent (20%) manifestations.[4,22] Diarrhea is watery and explosive,[13] with patients having up to 15 stools during the first day. Shock caused by loss of fluid is an exceptional event.[25] Mucus is observed frequently, but grossly bloody stool is seen less commonly.[9,40,49] Small superficial ulcerations on sigmoidoscopy may be present.[9] No difference in symptoms exists in cases associated with KP-negative strains.[37]

Extraintestinal infections occur. During the Vibrio Surveillance Program that started in 1989 in four Gulf Coast states, 18 to 34 percent of *V. parahaemolyticus* isolates were found to come from wound infections, and 3 to 5 percent were found to be associated with septicemia.[23,49] In 2009, 11 percent of isolates from the United States were obtained from wounds and 2 percent of isolates from blood cultures.[17] Wound infection occurs after contamination of skin lacerations with seawater or after direct trauma with pieces of shellfish, fishhooks, or utensils contaminated with seawater.[10] Superficial infection can extend to deeper soft tissue and in some cases lead to fatal necrotizing fasciitis.[67] Septicemia is a concern in immunocompromised patients, particularly patients with leukemia[27] and patients with liver disease.[26,36] Bacteremia may develop after either wound infections[10,27] or ingestion of seafood.[36,70] Skin bullae,[36] intravascular hemolysis,[27] and disseminated intravascular coagulation[36] may complicate wound and bacteremic infections.

COMPLICATIONS

An acute diarrhea episode requires medical attention in 25 to 50 percent of cases during an outbreak, but less frequently requires hospitalization.[12,22,49,74] Children younger than 5 years of age are more likely to require hospitalization in contrast to individuals older than 5 years.[79] Usually, no long-term sequelae occur. Severe dehydration, shock,[40,68] and death (0.04% of cases in Japan) can occur.[8,82] Primary septicemia,[47,49,70] septicemia secondary to wound infection,[10,27,47] and septicemia secondary to gastroenteritis[36,47] have higher mortality rates, especially in immunosuppressed patients or in patients with liver diseases.[10,30]

DIAGNOSIS

Epidemiologic data are the basis for the presumptive diagnosis. In a patient with compatible symptoms, a history of recent consumption of seafood should suggest this diagnosis. Leukocytosis and fecal leukocytes may be found.[9,40] A positive stool culture on selective media, such

as TCBS agar, can confirm the clinical impression. Routine use of TCBS agar is not cost-effective, even in coastal areas, unless an appropriate clinical setting is available.[10,49,54] The use of a transport medium, such as Cary-Blair, is necessary if a delay in processing the sample is expected. Isolation of more than 10^5 *V. parahaemolyticus* from epidemiologically implicated food supports the diagnosis and identifies the vehicle.[54] A correlation between the serotype of the food and isolates from patients is not always present because multiple strains can contaminate a single food.[4] Adding an enrichment broth to the processing increases the yield of isolation.

For testing blood specimens, use of routine culture media followed by selective media is appropriate.[36,70] Immunoassays (enzyme-linked immunosorbent assay, immunoprecipitation in agar medium, reversed passive latex agglutination) are available in research laboratories and commercially in Japan (KAP-RPLA, Denka Seiken, Tokyo; BT test, Nissui Pharmaceutical, Tokyo) to detect the TDH. Strains producing TRH may be detected by cross reactions.[87] Serologic methods (slide agglutination) can detect H antigens in lateral flagella.[72] Gene probe hybridization[62] and polymerase chain reaction with a sequence of a highly conserved DNA fragment[48] or targeting the *tdh* or *trh* genes can be used to detect low numbers of the organism in environmental and clinical specimens,[45,46] but these methods are usually limited to research laboratory settings. Histologic findings from duodenal and rectal biopsy samples from patients infected with *V. parahaemolyticus* were consistent with acute inflammatory response, showing epithelial degradation, polymorphonuclear neutrophil infiltration of villi and crypt cells, and hemorrhage.[69]

TREATMENT

Only supportive therapy and careful control of the fluid and electrolyte balances are required for the management of gastroenteritis. Oral rehydration usually is appropriate, although intravenous fluids may be required if massive losses of fluid occur.[9,40,68] Antibiotic therapy is unnecessary for this short-lived disease. In the unusual protracted episode, tetracycline or a fluoroquinolone may be beneficial for adults and older children.[8,9,43]

For wound infections and septicemia, antibiotics are always indicated. Patients with septicemia should be treated with a tetracycline plus a third-generation cephalosporin. *V. parahaemolyticus* usually is susceptible to tetracycline. In addition, only a few clinical strains are resistant to chloramphenicol, trimethoprim-sulfamethoxazole, third-generation cephalosporins, aztreonam, imipenem, fluoroquinolones, and aminoglycosides.[10,27,32,36] Penicillins are ineffective because of the presence of β-lactamases in 50 percent of isolates.[32,44] The older cephalosporins also have poor activity.[44]

PREVENTION AND CONTROL

Although ensuring the lack of contamination of seafood is impossible, avoiding food-handling errors should diminish the risk for infection. A recommendation for an acceptable upper limit of 100 colony-forming units per gram of *V. parahaemolyticus* in raw shrimp has been made by the International Commission on Microbiological Specification for Foods.[41] Thorough cooking eliminates the organism.[80] Heating seafood to 60°C (156.2°F) for 15 minutes[28] or boiling for 7 minutes[12] seems to be adequate to reduce the risk for infection. When undercooked or raw seafood is consumed, adequate prior refrigeration to preclude multiplication of organisms is important. During the preparation of seafood, special attention should be paid to possible cross-contamination. Use of the same utensils, board surfaces, or containers for fresh and recently cooked seafood should be avoided.[68,80] Raw seafood consumption should be discouraged, particularly for individuals at high risk for development of septicemia.[26,47,49]

CHAPTER 119

Vibrio vulnificus

Randall G. Fisher

BACTERIOLOGY

Vibrio vulnificus is a small, curvilinear, gram-negative rod of the family Vibrionaceae.[7] This facultative anaerobe is oxidase-positive and lysine-positive, similar to other species of the genus *Vibrio*. Its major difference is that it ferments lactose, a feature that accounts for its original name, Lac + *Vibrio*. *V. vulnificus* is arginine-negative and ornithine-variable. This halophilic (salt-loving) organism grows in concentrations of sodium chloride of from 1 to 8 percent and seems to grow best at approximately 3 percent.[37]

EPIDEMIOLOGY

V. vulnificus, similar to *Vibrio parahaemolyticus*, is a marine organism that is a common inhabitant of off-shore waters, especially estuarial waters.[57] It has been isolated from sediment, plankton, water, finfish, crabs, and oysters.[65] Peak recovery occurs in the summer and early fall,[18] possibly because at higher water temperatures *V. vulnificus* is released and rises to surface waters. There it attaches to plankton and shore fish and then is taken up and concentrated by filter-feeding mollusks and crustaceans.

V. vulnificus has been isolated from wild and commercial oysters throughout the world. It especially is prevalent in warm coastal waters. Reports about the survival of the organism in oysters stored at low temperatures are conflicting.[31] Nilsson and associates[55] revealed, however, that even if *V. vulnificus* is rendered nonculturable by storage at low temperatures, it can be "resuscitated" by allowing the oysters to warm up to room temperature; this cycle could be carried out twice without any reduction in bacterial count. Because of the ubiquity of the organism in the marine environment and its ability to thrive under even the most careful conditions of sanitation, storage, and transport,[17,35] ensuring that commercial shellfish do not contain viable *V. vulnificus* is very difficult.

So-called heat shock shucking, during which the internal meat temperature exceeds 50° C (122° F) for 1 to 4 minutes, reduces the *V. vulnificus* and total bacterial levels in oysters 10-fold to 10,000-fold compared with conventional processing.[23] A separate study confirms that low-temperature pasteurization, which brings oyster temperatures to 50° C for 10 to 15 minutes, reduces colony counts from greater than 100,000/g of oyster meat to undetectable levels.[2] Ice immersion for 3 hours is ineffective at reducing *V. vulnificus* and actually increases coliform counts in oysters.[56,60] High-pressure processing is a promising new approach to eliminating *V. vulnificus* from oysters; in preliminary studies, *V. vulnificus* could be reduced to undetectable levels by processing at 586 MPa with a 7-minute "come up" time.[38]

Disease in humans is initiated by contact with the organism. Contact occurs either through marine contamination of a wound or in the gastrointestinal tract after ingestion of the organism in raw shellfish, most commonly oysters.[7]

PATHOPHYSIOLOGY

V. vulnificus causes three distinct diseases in humans: wound infection and gastrointestinal infection, which may be self-limited or progress to septicemia. Local infection occurs after a wound is exposed to contaminated sea water. Wound infections with *V. vulnificus* are marked by rapid spread, the formation of bullae, and necrosis of involved tissues.[7] Marked edema and vascular thromboses occur in experimental and natural infection. *V. vulnificus* elaborates a cytolysin,[21,22,37,40] a collagenase,[63] and a protease,[50] which enhance its rapid spread in tissues. The protease activates the plasma kallikrein-kinin system to produce bradykinin[49]; histamine also is released locally. These factors account for the intense inflammatory reaction seen in these lesions. One group of researchers constructed an isolate that lacked a flagellum and found that its ability to adhere to cells was decreased, as was its lethality in mice.[42] Hemorrhagic complications may be due to the presence of a metalloprotease that interferes with blood homeostasis through prothrombin activation and fibrinolysis.[11]

In otherwise healthy individuals, a mild, self-limited gastrointestinal illness similar to that caused by *V. parahaemolyticus* has been described.[36] The most serious infection produced by *V. vulnificus* is primary septicemia, which occurs most commonly in patients with liver disease, after they have ingested the organism in raw shellfish.[7,58,59]

For patients with hepatic disease, the risk for acquiring septicemia is 40 to 80 times greater, and the case-fatality rate is 2.5 times higher than for otherwise healthy individuals.[25] *V. vulnificus*, similar to many other gram-negative organisms, requires iron for growth and grows better in an excess of iron.[73] It is able to extract iron from hemoglobin, even if it is complexed completely to

haptoglobin.[73,76] Liver damage, excess iron, and deferoxamine therapy have been shown to decrease the median lethal dose (LD_{50}) of *V. vulnificus* in experimental animals. Deferoxamine alone decreased the LD_{50} by four orders of magnitude.[9] Iron overload almost certainly underlies *V. vulnificus* septicemia in patients who require repeated transfusions and deferoxamine therapy for anemia.[30,75] Some evidence indicates that alcoholism, even in the absence of demonstrable liver disease, is a risk factor for developing sepsis.[58] Fatal septicemia has been reported in patients with other chronic diseases, such as diabetes mellitus and lymphomas.[59]

Virulence factors of the organism have been described.[74] Virulent strains are resistant to the bactericidal activity of human serum,[39] probably because of the presence of a polysaccharide capsule.[1] Poor uptake of virulent strains into phagocytes[66] and opaqueness of the colony on agar have been correlated with the presence of the capsule.[62,74] RTX toxin is a cytolysin that also may be important in protecting the organism from phagocytosis.[44] No difference has been shown in the lipopolysaccharides of virulent versus avirulent strains.[5] The production of recalcitrant shock in patients with septicemia is secondary to toxins, loss of vascular tone, capillary leak, and possibly negative inotropy, as in other forms of gram-negative sepsis.

CLINICAL MANIFESTATIONS

Patients commonly have wound infection or primary septicemia. Wound infection occurs after injury in sea water or after the contamination of a recently acquired wound with sea water. Often, the wound is caused by the shell of a crustacean or mollusk. Many patients with wound infections work in shellfish-related industries. Apparently, wound infection with *V. vulnificus* can develop from superficial wounds acquired within 24 hours of "uneventful" fish handling; the physiologic characteristics of human sweat may be conducive to the survival of the organism on the skin, allowing for later inoculation.[10] Cellulitis may develop and spread rapidly. Overlying skin often is covered with tense bullae. At débridement, the extent of necrosis may exceed presurgical expectations.[72] Primary wound infection may progress to systemic infection; for this reason, wound infection with *V. vulnificus* carries a mortality rate of 7 to 24 percent.[7,36] Findings associated with mortality in patients with necrotizing fasciitis include low white blood cell counts, low platelet counts, hypoalbuminemia, high immature neutrophil percentages, and hypotension at presentation.[69]

Patients with primary septicemia generally give a history of recent (i.e., 6 to 72 hours) consumption of raw seafood. Illness is marked by the rapid onset of fever, hypotension, and septic shock. Prodromal symptoms, such as malaise, chills, and fever, are common manifestations. Vomiting and diarrhea are seen in approximately 20 percent of patients.[6] Shock progresses quickly and is difficult to reverse. Secondary skin lesions develop in approximately half of patients[7] and may be bullous, petechial, or maculopapular. *V. vulnificus* frequently is isolated from cultures of secondary lesions, providing evidence of septicemic spread to those sites.[7] The mortality rate from primary septicemia has been reported to be 46 to 79 percent.[6,58]

In addition to causing the described syndromes, *V. vulnificus* has been reported as a cause of corneal ulcer,[19] myositis,[32] adult epiglottitis,[46] osteomyelitis,[70] endocarditis,[68] peritonitis,[27] tubo-ovarian abscess,[47] and meningitis.[30,58] In one case, a patient had endogenous endophthalmitis without systemic symptoms that developed after ingestion of raw seafood.[29] A case of fatal septicemia in which the presenting symptom was a compartment syndrome of the forearm has been described.[28] A 9-year-old girl with thalassemia and iron overload had septic arthritis as the presenting feature of her septicemia.[41] Ninety percent of reported patients are 40 years old or older.[7,58] Childhood cases of septicemia have been associated with thalassemia major,[29] for which frequent transfusions and deferoxamine therapy are required. Wound infections in previously healthy children and adolescents have been reported. *V. vulnificus* also has been isolated from a premature infant's stool sample obtained on the infant's first day of life; the infant's mother worked as an oyster shucker.[4]

DIAGNOSIS

The diagnosis of *V. vulnificus* infection is made by isolating the organism from blood or tissue culture. It also may be recovered from stool specimens.[4,59] Agars designed specifically to aid in the growth and identification of *V. vulnificus* have been developed; cellobiose-colistin agar out-performs thiosulfate citrate bile salts sucrose agar (TCBS) for recovery of *V. vulnificus* from environmental samples.[26] From a practical standpoint, however, most hospital microbiology laboratories do not stock cellobiose-colistin agar. Of the commercially available media, *V. vulnificus* tends to grow best in TCBS,[7] but it also may be recovered from ordinary blood agar plates[3,61] or MacConkey plates.[7]

A very sensitive nested polymerase chain reaction technique that is capable of detecting 1 pg of bacterial DNA and one colony-forming unit of *V. vulnificus* has been described; it was positive in 94 percent of clinical samples that grew the bacteria in culture and in 42 percent of culture-negative samples from patients with suspected *V. vulnificus* infection.[24,43] A newer multiplex PCR was developed that had 100 percent sensitivity and specificity for identification and differentiation of *V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus* in validation tests with 488 strains.[53] An enzyme immunoassay also has been developed.[66] These methods are experimental and not yet available for routine clinical use.

The diagnosis of *V. vulnificus* wound infection or septicemia can be suspected on clinical grounds and appropriate therapy initiated while awaiting culture results. A history of ingestion of raw shellfish or contamination of a wound with either sea water or brackish inland waters[64] should be sought. *V. vulnificus* infection should be given high consideration in patients with hemosiderosis, anemia with transfusion therapy, liver disease, or other chronic diseases.

TREATMENT

For severe wound infections, performing surgical therapy as rapidly as possible is paramount. For primary septicemia, support of the patient's airway, along with aggressive pressor support and other adjunctive therapies for severe septic shock, is of primary concern. Secondarily, appropriate antibiotic treatment for *V. vulnificus* should be started as early as possible.[51]

In vitro, the organism is susceptible to many antibiotics, including ampicillin, third-generation cephalosporins, tetracycline, chloramphenicol, and gentamicin.[7] Bowdre and associates[8] reported that in mice the minimum inhibitory concentrations obtained in the laboratory did not seem to correspond with response to therapy. In particular, the organism seemed to be exquisitely sensitive to cefotaxime in vitro (minimum inhibitory concentration 0.06 μg/mL); however, 9/10 mice treated with cefotaxime died of overwhelming infection. Anecdotal evidence indicates that this puzzling phenomenon may occur in humans as well; 4/5 patients reported by Chuang and associates[15] died, despite receiving therapy with third-generation cephalosporins at appropriate dosages. Similarly, although the organism is almost universally sensitive to gentamicin in the laboratory, case reports show a lack of response to this antibiotic. Of all the antibiotics to which the organism was sensitive in vitro, only tetracycline led to survival of mice in Bowdre's study; all 12 of the mice treated with tetracycline survived the infection.[8]

Case reports also show favorable outcomes with tetracycline[20] or doxycycline[15] and chloramphenicol[15] and ciprofloxacin.[45] More recently, the combination of minocycline and cefotaxime has been shown to be synergistic in vitro, with the combination reducing the growth of *V. vulnificus* by six orders of magnitude in contrast to either drug alone.[14] Enhanced survival of mice infected with *V. vulnificus* and treated with minocycline plus cefotaxime provides an in vivo correlate of the in vitro results.[16] No data are available comparing the activity of minocycline and that of tetracycline; nonetheless, the previously mentioned evidence is sufficiently strong to suggest that either tetracycline or minocycline together with cefotaxime should be the treatment of choice for known or suspected *V. vulnificus* infection. Fluoroquinolones also may have a role in treatment. In vitro synergy studies show that the combination of ciprofloxacin and cefotaxime is synergistic for *V. vulnificus*,[34] and in a murine model, the newer fluoroquinolones (e.g., moxifloxacin) worked as well as combination therapy in preventing lethality in mice.[13] As yet, no human clinical data are available regarding the efficacy of third-generation fluoroquinolones. In vitro, the addition of the iron chelator deferasirox to antimicrobial treatment (in this study, ciprofloxacin) resulted in synergistic antimicrobial activity.[54] One case has been reported of a patient iron-overloaded from hemochromatosis who survived after treatment with the combination of ciprofloxacin and deferasirox.[33]

The addition of modified Dakin solution (0.025% sodium hypochlorite) may have some utility in the treatment of skin and wound infections. An in vitro study of eight topical antibiotic preparations showed that *V. vulnificus* was most sensitive to modified Dakin solution.[48] Although no controlled trial has been performed, a series has been reported of 10 patients with culture-proved *V. vulnificus* wound infections treated with doxycycline and topical modified Dakin solution, none of whom experienced progression of infection or required surgical débridement.[71] Autologous platelet concentrate spray was used successfully as adjunctive wound therapy in a renal transplant patient.[67]

PREVENTION

Patients with severe anemia, liver disease, hemosiderosis, or other debilitating chronic diseases and patients on deferoxamine therapy should be advised against eating raw seafood of any kind. Awareness of the disease has been shown to be low in high-risk patients; physicians need to educate at-risk patients.[52] Patients with open wounds probably should avoid contact with sea water or brackish inland waters. In a mouse model, intramuscular VvpE (a recombinant metalloprotease antigen of *V. vulnificus*) elicits a good antibody response and confers protection against lethal challenge.[12]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 120

Miscellaneous Non-Enterobacteriaceae Fermentative Bacilli

Randall G. Fisher

Fermentative bacilli that are not of the family Enterobacteriaceae are discussed in this chapter. Specifically examined are *Chromobacterium violaceum*, *Plesiomonas shigelloides*, and *Pasteurella* organisms other than *Pasteurella multocida*.

CHROMOBACTERIUM VIOLACEUM

C. violaceum is a facultatively anaerobic, gram-negative rod that is a saprophyte of soil and water and especially is found in tropical and subtropical climates. It causes occasional illness in animals and, rarely, in humans. Infection with *C. violaceum*, when it does occur, is a serious disease with a high mortality rate.

Bacteriology

C. violaceum is a long, motile, gram-negative bacillus that appears singly or in pairs on Gram stain. It has a polar flagellum and one to four subpolar or lateral flagella that antigenically are distinct from the polar flagellum.[85] Most isolates produce an insoluble pigment, violacein. This pigment is intense and makes colonies appear dark purple to black, especially on blood agar. Violacein induces apoptotic death in certain cell types in vitro, including leukemia and lymphoma cells.[65] The therapeutic potential of violacein and structural analogs is being explored. Violacein also has antibacterial, antitrypanosomic, antimalarial,[58] and weak antiviral effects.[8] In a rat model, violacein displays immunomodulatory, analgesic, and antipyretic effects[9]; in addition, it protects against gastric ulcers and is an effective treatment for diarrhea.[10] *C. violaceum* grows readily on standard agar (any medium that contains tryptophan supports growth). The colonies are low convex, violet, smooth, and not gelatinous. Colonies produce hydrogen cyanide, so a faint almond odor may be present.[85]

C. violaceum is catalase-positive and oxidase-positive, although the latter may be difficult to interpret because of the production of pigment. Growing the organism anaerobically inhibits pigment formation.[52] Pigment also may be lost on subculture[75] or as effective treatment is initiated. *C. violaceum* has a fermentative, not oxidative, attack on carbohydrates.

Epidemiology

C. violaceum commonly is found in soil and water of areas with tropical or subtropical weather patterns. It also has been recovered from soil as far north as New Jersey.[23] Ten of the first 12 cases reported in the United States occurred in Florida; the other two were in Louisiana. Subsequently, one case from New Jersey[70] and one from Ohio[87] have been reported, along with more from southeastern states. All but one case occurred during summer.[75] Patients tend to be young, with a median age of 14 years.[75]

Pathophysiology

Although *C. violaceum* is a common inhabitant of soil and water, human infection is rare. Disorders of neutrophil function are important risk factors. A disproportionately high number of *C. violaceum* infections have occurred in patients with chronic granulomatous disease.[60] *C. violaceum* infection in a child with another disorder of neutrophil function, polymorphonuclear leukocyte glucose-6-phosphate dehydrogenase deficiency, has been reported.[61] Organisms may show variable virulence, and differences in endotoxin activity, resistance to phagocytosis, and production of catalase and hydrogen peroxide have been observed between clinical and soil isolates.[67] An elastase activity, expressed through the entire life cycle and produced by a zinc metalloproteinase, may account for the propensity of *C. violaceum* to cause abscesses.[102] Because *C. violaceum* is a free-living organism that is exposed to diverse environmental conditions, it exploits a wide range of energy resources and is able to thrive in aerobic and anaerobic conditions.[22] It is equipped to be tolerant of harsh conditions, including acid and ultraviolet stress, temperature stress, heavy metal exposure, and antibiotic exposure.[44] The complete sequencing of its genome has allowed researchers to identify putative virulence genes that are likely involved in host cell adhesion, cell invasion, and cytolysis.[15] Cytotoxicity is caused by pore formation on host cell membranes; this is mediated by a type 3 secretion system product of pathogenicity island 1.[66] A *Serratia*-type hemolysin has also been described.[17] *C. violaceum* is able to produce an exopolysaccharide biofilm.[12]

The organism usually gains entrance to the body through cuts or abrasions that come in contact with contaminated soil or water. After entrance, a localized infection usually develops at or around the site of entry, which is commonly followed by dissemination of infection via the bloodstream to distant sites. Rapid débridement and appropriate antibiotic therapy may arrest the infection at the wound stage.[55] Two cases of systemic infection occurred in near-drowning victims. One case report describes fulminant infection and death in an immunocompetent host from *C. violaceum* sepsis that began as conjunctivitis after a fall that splattered mud into the patient's eye.[28] Numerous microabscesses are found in multiple organs, especially liver, lung, and kidneys. Spread to bone, joints, and the central nervous system also has been described.

Clinical Manifestations

The pattern of illness in all reported patients is similar, with a contaminated inoculation site, localized disease, regional lymphadenopathy, and hematogenous spread to visceral organs. Progression of symptoms tends to be rapid after a variable incubation period.

Most patients have cutaneous lesions,[60] which are described as being nodular or pustular and sometimes with surrounding cellulitis.[93] They may progress to suppuration and drainage or to ulceration. Occasionally, classic ecthyma gangrenosum lesions have been described.[16] Regional lymphadenopathy is common; some of the nodes suppurate and require surgical drainage or removal.

Severe disease is heralded by high fever (39° C to 41° C [102.2° F to 105.8° F]), confusion or lethargy, abdominal pain, headaches, nausea and vomiting, and sometimes myalgias. Patients with systemic illness appear toxic. Hepatosplenomegaly develops frequently, and jaundice may be present. Progression from high fever and moderate toxicity to septic shock with disseminated intravascular coagulation and multisystem organ failure is precipitous. After the liver, the lung is the most common site of dissemination of infection, and evidence of pneumonia often is found. Adult respiratory distress syndrome is rare.[56] Brain and liver abscesses have been noted.[68] The overall mortality rate is 65 percent.[60] Rarely, there may be recurrence, which can prove fatal.[52,75] A review of all 25 pediatric cases reported between 1971 and 2005 revealed, counterintuitively, that the case-fatality rate was 12 of 16 (75%) in patients without chronic granulomatous disease and in none of 9 in patients with a known diagnosis of chronic granulomatous disease.[83] One case in a patient with chronic granulomatous disease who suffered three separate episodes of *C. violaceum* sepsis has been reported.[89]

A review of all cases reported between 1952 and 2009 (n = 106) found that all patients had fever. Sepsis developed in 82 percent of patients. Localized abscesses were found in about half of the patients, with the liver being the most common site. Relapse occurred in 6.6 percent, with a median interval of 135 days. Risk factors for mortality were young age at diagnosis, the presence of a localized abscess, a shorter clinical course, and inappropriate initial antimicrobial therapy.[99]

Diagnosis

Diagnosis is made by recovery of the organism from blood, lymph nodes, skin lesions, or abscesses. Gram-negative bacilli sometimes can be seen in smears of material from skin lesions. Laboratory values reveal either very low or very high white blood cell counts with marked left shifts. Mild to moderate anemia is common. Serum levels of liver enzymes may be elevated, and evidence of early renal failure sometimes is present. The organism grows readily and is easy to identify if it produces the characteristic violet pigment. Nonpigmented forms exist in soil and have similar virulence in mice[84] but are recovered only rarely from clinical specimens.[87] Other cases may have been missed, however, because the nonpigmented forms often are misidentified as *Aeromonas hydrophila* or as pseudomonads.[84] Reports that *C. violaceum* infection causes a melioidosis-like illness were probably due to misidentification of *Burkholderia pseudomallei* by the API 20NE system.[45]

A clinical history of contamination of a wound with water or soil, especially in the southeastern United States or in Southeast Asia, with subsequent local infection, lymph node suppuration, and lack of response to conventional antibiotic therapy, should arouse suspicion of *C. violaceum* infection. The clinician particularly should be aware of the possibility of *C. violaceum* infection in patients with chronic granulomatous disease.

Treatment

C. violaceum is sensitive in vitro to chloramphenicol, gentamicin, fluorinated quinolones, tetracyclines, imipenem, trimethoprim-sulfamethoxazole, and semisynthetic penicillins. *C. violaceum* often is resistant to cephalosporins, penicillin, ampicillin, and the antistaphylococcal penicillins. All isolates are resistant to vancomycin and rifampin.[5] Some strains have been shown to elaborate a β-lactamase, which is chromosomal and inducible in vitro.[27] At least one case report gives in vivo evidence of inducible resistance to ceftazidime.[93] Laboratory evidence of susceptibility to erythromycin cannot be relied on. In vitro, the fluoroquinolones have the highest activity.[5] Clinical experience with the fluoroquinolones in *C. violaceum* infection is scarce; an impressive case of a 4-month-old infant with severe disseminated *C. violaceum* infection who survived after therapy with trimethoprim-sulfamethoxazole and ciprofloxacin has been reported.[68] The review of 25 cases mentioned earlier found that all survivors had been given one or a combination of the following agents: ciprofloxacin, trimethoprim-sulfamethoxazole, chloramphenicol, or imipenem.[83]

Because infection with *C. violaceum* is rare and often rapidly fatal, optimal antimicrobial therapy is unknown. Duration of therapy also is unknown, but because of late recurrences, some authors recommend 3 to 4 weeks of intravenous therapy followed by 1 month or more of oral trimethoprim-sulfamethoxazole.[75]

PLESIOMONAS SHIGELLOIDES

Plesiomonas shigelloides is the only species for the genus *Plesiomonas.* These organisms are facultatively anaerobic, motile, gram-negative rods that are common inhabitants of surface water and fish. They have been implicated in gastrointestinal infections and, rarely, have been recovered from extraintestinal sites.

Bacteriology

P. shigelloides is a member of the Vibrionaceae, although some authorities suggest it is related more closely to Enterobacteriaceae.[59] The organisms are motile by means of a polar flagellum. They are lysine positive, ornithine positive, and arginine decarboxylase positive. They can be distinguished from Enterobacteriaceae by oxidase positivity. They also are catalase positive and indole positive. They grow well on MacConkey agar but not on thiosulfate citrate bile salts sucrose (TCBS) agar. Growth may be enhanced by the use of selective media, such as trypticase soy broth with ampicillin[76] and inositol brilliant green–bile salts agar. Growth is maximal at 40° C to 44° C and completely inhibited at 8° C. Usually within 24 hours, 1.0- to 1.5-mm grayish, shiny, opaque colonies with a slightly raised center and a smooth surface are visible. A few isolates of *P. shigelloides* share a common O antigen with *Shigella sonnei.*

Epidemiology

The organism is a ubiquitous freshwater inhabitant at temperatures greater than 8° C. It sometimes also is found in estuarial waters in temperate or tropical climates and can exist in sea water during the summer. It has been cultured from finfish, shellfish, pigs, birds, and dogs.[97] Although infection with *P. shigelloides* has been associated with ingestion of raw or improperly cooked fish (especially oysters), it is unknown what role, if any, other animals play in the ecology of the organism. Asymptomatic carriage of *P. shigelloides* is rare in developed countries[79] but may be 15 percent in some parts of China.[97]

Pathophysiology

Despite the ubiquity of the organism in nature, human infection is uncommon and has been recognized only more recently. Most often, infection is associated with gastroenteritis. Evidence for the role of *P. shigelloides* in the production of gastrointestinal symptoms is that it has been isolated much more frequently from patients with diarrhea than from healthy control subjects[42]; there have been some outbreaks, especially in Japan; it often is the only organism detected in the stools of patients with gastroenteritis[64]; and patients who have *P. shigelloides* growing from a stool culture recover more quickly with than without antibiotic therapy.[49] Acquisition of disease has been linked specifically to consumption of raw seafood or untreated water and to foreign travel, especially to Mexico.[39,63]

The mechanism by which the organism produces disease has been elusive. It is not enteroinvasive by laboratory tests, most investigators fail to find either a Shiga toxin or an enterotoxin,[1,39] no animal model of gastrointestinal disease has been found,[14] patients in the recovery phase do not show serologic evidence of infection, and inoculation of volunteers fails to produce illness.[39] In a suckling gnotobiotic piglet model in which the animals became septic, histology of the gastrointestinal tract showed neither destruction of cells nor invasion of tissues.[39] Neonatal BALB/c mice became chronically infected with *P. shigelloides*, however, and histopathologic findings included some cases of necrosis of the mucosal surface of the ileum and colon.[96]

Some potential virulence factors (i.e., a cholera-like toxin, a weak cytolysin, serum resistance, and a large [>150-kDa] plasmid) have been described, but their exact roles in pathogenesis are uncertain; attempts to correlate these features with virulence have been fruitless.[1] Investigators have characterized a cytotoxin derived from *P. shigelloides* using strains from patients with a diarrheal illness. The cytotoxin is a complex of three lipopolysaccharide-binding proteins and lipopolysaccharide in a 6:5 ratio.[72] Cytotoxic activity was inhibited 80 percent in vitro by proteinase K or when incubated with anticholera toxin antibody. This cytotoxin produced a positive reaction in the suckling mouse assay, whereas the purified lipopolysaccharide exhibited almost no cytotoxicity.[72]

Transmission electron microscopy has provided investigators with the first definitive proof that *P. shigelloides* can adhere to and invade eukaryotic intestinal cells. Organisms attached to microvilli and plasma membranes of the cells; they also were seen within vacuoles in the cell cytoplasm, suggesting a phagocytotic entry mechanism.[91] In one in vitro system using Caco-2 cells, adherence occurred within 10 minutes and internalization occurred within 60 minutes. Cytotoxicity was due to the induction of apoptosis.[94] In vitro, cell-free and cell-associated hemolysis is demonstrable,[35] and low levels of elastase, proteinase, histidine decarboxylase, and moderate levels of triacylglycerol lipase activity have been found.[21] Culture filtrates are capable of inducing vacuolation of a variety of mammalian cells in vitro.[26]

P. shigelloides rarely, but more clearly, is a pathogen in extraintestinal sites. Osteomyelitis, endophthalmitis, cholecystitis, pseudoappendicitis, spontaneous peritonitis,[4] meningitis,[90] and septicemia have been reported sporadically.[14] Most patients with septicemia have been immunocompromised hosts, but the organism has been isolated from blood cultures in otherwise healthy individuals.[46,74] The mode of infection in extraintestinal sites is unclear, but most cases are thought to arise from the gastrointestinal tract. The case of a newborn with *P. shigelloides* meningitis, septicemia, and endophthalmitis who was born to a mother who reported severe diarrhea after eating raw oysters 2 weeks before delivery raises the possibility of transplacental transmission.[62]

Clinical Manifestations

Patients with *P. shigelloides* gastroenteritis complain of diarrhea, crampy abdominal pain, nausea and vomiting, headache, and fever. Symptoms usually begin 24 hours to

4 days after contact with the organism.[42] Diarrhea tends to be secretory, although some patients have symptoms more consistent with colitis.[49] Passage of blood, mucus, or both in the stools is a common manifestation, as is the presence of white blood cells by Wright stain.[42] Patients with *P. shigelloides* gastroenteritis tend to have disease that is more acute, associated with more severe abdominal pain, and of longer duration than patients with diseases caused by other enteropathogens.[49]

In one case-control study, 76 percent of patients were sick for more than 2 weeks and 32 percent were sick for more than a month.[49] In contrast, a large Japanese study of returning travelers suggested that for most patients the symptoms abated within approximately 3 days.[82] In a series of 38 pediatric cases in Bangladesh, 84 percent had secretory diarrhea and 71 percent had associated emesis. Only three patients (8%) had fever, and only five (13%) had diarrhea for 14 days or longer.[54] In a separate report, one child developed migratory polyarthritis during an otherwise typical case of culture-proven gastrointestinal infection. All symptoms and signs of arthritis disappeared when the gastrointestinal infection was treated with antibiotics.[36]

Localized extraintestinal infections have been reported but are rare. Two cases of severe polymicrobial endophthalmitis resulting from fishhook trauma progressed to enucleation.[18] Two cases of peritonitis associated with continuous ambulatory peritoneal dialysis were reported from Hong Kong. Both patients recovered after 10 days of therapy with intraperitoneal cefazolin and tobramycin.[98] In one odd case, a woman had pyosalpinx from *P. shigelloides* thought to have been acquired by swimming in contaminated water.[80] A cavitary pneumonia was found in a 78-year-old woman who underwent gastrectomy and esophagojejunostomy because of adenocarcinoma of the stomach. Biopsy showed granulomatous changes.[81] One patient developed a skin abscess after incurring trauma in fresh water.[40]

Septicemia, meningitis, or both usually occur in immunocompromised hosts. Severe, rapidly progressive sepsis complicated by disseminated intravascular coagulation, adult respiratory distress syndrome, renal insufficiency, hepatic dysfunction, adrenal hemorrhage, and splenic abscess has occurred in patients with hemoglobinopathies and absence of splenic function, including thalassemia intermedia and sickle-cell disease.[7,95] Unusual sites of infection sometimes are noted in immunocompromised individuals, such as epididymo-orchitis in a patient with human immunodeficiency virus infection.[101] Newborns constitute most of the reported cases of *P. shigelloides* meningitis, in whom the mortality rate is 80 percent.[1] Cerebrospinal fluid parameters may be normal, even when the culture is positive.[73] Septicemia also has a high mortality rate in adults, although otherwise well patients may recover with appropriate antimicrobial therapy.

Diagnosis

A clinical history of foreign travel or of ingestion of raw seafood or untreated water should raise suspicion of possible *P. shigelloides* infection, especially when the clinical illness matches the description just mentioned. Oxidase tests should be done on any predominant or solitary organisms to distinguish them from Enterobacteriaceae.[42] The organisms can be shown not to be aeromonads or pseudomonads by production of ornithine decarboxylase and fermentation of inositol. Selective medium can be used if the index of suspicion is high. A new indicator medium (UNISC agar) for the identification of *Aeromonas* and *Plesiomonas* has been developed; colonies turn yellow if xylose is fermented and turn blue if it is not.[78]

Treatment

Most strains of *P. shigelloides* produce a β-lactamase,[77] which seems to be specific for the penicillins. In one study, all isolates were resistant to ampicillin, ticarcillin, carbenicillin, and piperacillin.[32] *P. shigelloides* is universally susceptible to trimethoprim-sulfamethoxazole, the fluoroquinolones, most cephalosporins, carbapenems,[88] tetracycline,[88] and chloramphenicol. It is variably susceptible to the aminoglycosides and mostly resistant to erythromycin.[48]

P. shigelloides gastroenteritis resolves without therapy, but the illness may be prolonged. Treatment seems to shorten the course.[49] Extraintestinal infections carry a poor prognosis and should be treated aggressively. For meningitis, cephalosporins and carbapenems have good cerebrospinal fluid penetration and are effective therapy against most isolates.

OTHER PASTEURELLA ORGANISMS

The genus *Pasteurella* consists of a group of pleomorphic, gram-negative coccobacilli that are part of the normal flora of many animals. These organisms are frequent animal pathogens. *P. multocida* is a common human pathogen and is discussed in Chapter 116. The other species of the genus *Pasteurella* are rare but occasionally cause serious infection in humans.

Bacteriology

These organisms, similar to *P. multocida*, grow readily on most common laboratory media, including blood agar. Most of the species do not grow on MacConkey agar. They are non–spore forming, nonmotile, aerobic, and facultatively anaerobic. These glucose-fermenting organisms all are oxidase positive. Most are nitrate positive and catalase positive, and all except *Avibacterium gallinarum* (formerly *Pasteurella gallinarum*, see later) produce indole. They are small, coccoid or rod-shaped bacilli that may show prominent bipolar staining on Gram stain. Colonies are small, translucent, and gray and may be smooth or rough. A browning discoloration may develop around them, and they are nonhemolytic and have a distinctive musty or "mushroom" odor.[20]

The taxonomy of these organisms is confusing and continues to be revised. *Pasteurella ureae* and *Pasteurella pneumotropica* have been moved into the genus *Actinobacillus*. *Pasteurella haemolytica* has been reclassified into a new

genus, *Mannheimia*.[11] *Pasteurella dagmatis* is the name now given to what formerly was called *P.* new species, or P. "gas."[69] *Pasteurella gallinarum*, *Pasteurella avium*, and *Pasteurella volantium* have 96.8 percent sequence similarity and are phenotypically separate from other *Pasteurella* spp.; this feature has led to a proposal that they be moved into a new genus, *Avibacterium*.[13] Most experts agree that the genus *Pasteurella sensu stricto* should include *P. multocida*, *Pasteurella canis*, *Pasteurella stomatis*, and *P. dagmatis*.[50] *Pasteurella* spp. B has now been reclassified as *P. oralis* sp nov.[19] Clinically recovered species other than *P. multocida* include *Actinobacillus ureae*, *Mannheimia haemolytica*, *Actinobacillus pneumotropica*, *P. dagmatis*, *P. canis*, *Pasteurella aerogenes*, *Pasteurella bettyae*, *P. "SP"* group, and *P. stomatis*. *Pasteurella caballi* has caused wound infections after horse bites.[24] *Avibacterium gallinarum* is an extremely rare pathogen in humans.

Pathophysiology

Infection with *Pasteurella* spp. has been divided clinically into three types of infection: (1) from animal bites, (2) from animal contact,[31] and (3) without known animal contact.[22] Infections from animal bites include cellulitis, abscesses, tenosynovitis, and bone and joint infection, but infection can become generalized, especially in patients who are immunocompromised. Infections caused by animal contact can be similar to infections described earlier and are caused by animals licking broken skin or wounds. Sometimes pulmonary infections occur, possibly related to aerosolization of organisms. In some cases, these organisms have been reported as respiratory flora in patients with pets, but at present no proof exists that such colonization is an antecedent of infection.[29] Cases without known animal contact history constitute 3 to 30 percent of all cases.[43,47]

Infection usually occurs when the organisms are inoculated into deeper tissues either on animal teeth that break the skin or in animal saliva that comes in contact with nonintact skin. Bite wound infections often are polymicrobial. Infection in cases without known animal contact is harder to explain but definitely happens.[51] Most cases of serious infection occur in patients with underlying diseases, such as diabetes mellitus, chronic alcoholism, and other types of liver disease.[71] Central nervous system infection with these organisms has occurred after head trauma or neurosurgery in 10 of 11 reported cases.[51] One intrauterine death of the fetus of a 20-year-old woman who worked at a pig farm has been attributed to *P. aerogenes*.[92] Case reports of unusual infections with rare species of *Pasteurella*, such as fatal sepsis and meningitis in a 4-day-old infant caused by *A. gallinarum*,[2] should be considered doubtful unless molecular identification methods have been used.[38]

Clinical Manifestations

Pasteurella infections produce pain, swelling, pus, and sometimes abscess formation at the site of inoculation, beginning within 24 to 36 hours. Clinically, these infections are indistinguishable from wound infections with *Staphylococcus aureus* or other gram-positive organisms. Gram stain may show the characteristic pleomorphic bacilli with bipolar staining. Growth on standard agar is rapid.

Patients with peritonitis,[4,71] meningitis,[51] osteomyelitis,[32] or infectious endocarditis[6] have symptoms typical of these diagnoses. Risk factors, such as household pet exposure, animal contact, animal bites, and comorbid conditions, should heighten suspicion of possible *Pasteurella* infection. One report describes a previously healthy 21-month-old girl who developed *P. canis* bacteremia after exposure to rabbit saliva.[100] Bacteremia due to *P. canis* has also been described in a cirrhotic patient whose leg wound was licked by a dog.[3]

Diagnosis

Establishing the diagnosis of *Pasteurella* infection can be difficult, not because the organism is fastidious or slow growing but because it often is misidentified. Other organisms of the same family (i.e., *Actinobacillus* spp. and *Haemophilus* spp.) have similar biochemical profiles and can be misidentified by commonly used systems, such as API. Lester and associates[57] reported that of 30 species firmly identified as *Pasteurella* by biochemical means, only 3 were identified correctly by the API 20E system. *Actinobacillus* (*Haemophilus) aphrophilus* and *Actinobacillus actinomycetemcomitans* are sometimes misidentified as *Avibacterium gallinarum* by commercial systems.[30] Additionally, Hamilton-Miller[37] reported that four strains of *Haemophilus influenzae* and three strains of *Haemophilus parainfluenzae* were identified falsely as *Pasteurella* spp. by API and suggested that if the clinical history renders *Pasteurella* infection unlikely then tests for X and V factor requirements should be performed (see Chapter 133). Clinical case reports corroborate these laboratory observations.[25,71,86] Notifying the bacteriology laboratory of suspicion of *Pasteurella* infection is helpful.

Treatment

Penicillin has been considered the drug of choice for *Pasteurella* infection in the past and, despite some reports of penicillin resistance, still is effective against most strains. *Pasteurella* spp. also are susceptible to ampicillin, β-lactamase–inhibitor combination drugs, tetracycline, and chloramphenicol. Truncated but fully functional tetracycline resistance genes have been identified in isolates from animal sources.[53] The aminoglycosides, erythromycin, clindamycin, cefadroxil, and cefaclor are not recommended. Dicloxacillin and cephalexin have poor activity against *Pasteurella* spp. and should not be used as monotherapy for animal bite wounds.[33] In one study of bite wound infections, ertapenem was found to be active against all *Pasteurella* spp.[34] Of fluoroquinolones tested in vitro against 75 clinical isolates of *Pasteurella* spp., levofloxacin was the most active.[41]

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 121

Acinetobacter

Armando G. Correa

First recognized as a human pathogen in 1908,[79] the ubiquitous organism *Acinetobacter* has emerged as a rather common cause of nosocomial infections in immunocompromised hosts.[8] Some of the confusion regarding this organism may be attributed to the many changes in nomenclature that the members of this genus have undergone over the years. Names used in the past to identify this genus include *Herellea*, *Bacterium*, *Mima*, *Achromobacter*, *Alcaligenes*, *Neisseria*, *Micrococcus*, *Diplococcus*, *Moraxella*, and *Cytophaga*. Treatment of infection caused by *Acinetobacter* is complicated by its widespread multidrug resistance and the difficulty encountered in eradicating the organism.

THE ORGANISM

The genus *Acinetobacter* belongs to the Neisseriaceae, which also includes the *Neisseria*, *Moraxella*, and *Kingella* genera. *Acinetobacter* is a gram-negative bacterium that typically appears as a rod 0.9 to 1.6 μm in diameter and 1.5 to 2.5 μm in length, but it may become spherical in the stationary phase of growth. It frequently occurs in pairs or short chains. Many strains are encapsulated. The organism has a strictly aerobic respiratory metabolism and does not grow under anaerobic conditions. It does not form spores or exhibit swimming mobility. *Acinetobacter* grows well in all common complex media between 20° C and 30° C, with optimal growth occurring between 33° C and 35° C, and it has no growth factor requirements.

Convex, grayish white colonies 1.0 to 2.5 mm in diameter are typical findings. The colonies may appear mucoid if the strain is encapsulated. *Acinetobacter* is catalase positive and may be differentiated readily from other closely related genera by virtue of its negative reaction to oxidase.

Formerly, the genus *Acinetobacter* contained the single species *Acinetobacter calcoaceticus* subdivided into two subspecies or biovars: *anitratus* and *lwoffii*.[37] However, in 1986, the taxonomy of the genus *Acinetobacter* was changed extensively on the basis of DNA hybridization studies,[13] and at least 32 genomic species have been

proposed, of which 21 have been assigned species names.[19,51,52] At least 15 of these nomenspecies have been isolated from human specimens, including: *Acinetobacter baumannii*, *A. calcoaceticus*, *Acinetobacter haemolyticus*, *Acinetobacter johnsonii*, *Acinetobacter junii*, *Acinetobacter lwoffii*, *Acinetobacter radioresistens*, *Acinetobacter parvus*, *Acinetobacter schindleri*, and *Acinetobacter ursingi*.[17] Several genospecies that have been isolated from human clinical samples and had been given the provisional designation of genomic species 3, 13TU, 10, and 11 have now been named as *Acinetobacter pittii*, *Acinetobacter nosocomialis*, *Acinetobacter bereziniae*, and *Acinetobacter guillouiae*, respectively [51,52] *Acinetobacter soli*, a species previously isolated only from soil, has recently been implicated in an outbreak in a neonatal care unit.[57] These species may be difficult to differentiate in the clinical laboratory on the basis of their growth characteristics and biochemical activity. Because of their clinical relevance and antimicrobial resistance, four of these species, *A. baumannii*, *A. calcoaceticus*, *A. pittii* (formerly genomic species 3), and *Acinetobacter nosocomialis* (formerly genomic species 13TU), are grouped under the term *A. baumannii-calcoaceticus* complex. Under the new classification, most *A. baumannii* strains represent organisms that were classified formerly as biovar *anitratus*, whereas *A. junii* and *A. lwoffii* previously were listed under the biovar *lwoffii*.

EPIDEMIOLOGY

Acinetobacter strains are distributed widely in nature and can be found in soil, fresh water, and sewage.[10,31] *Acinetobacter* also can be isolated from many animals, fresh meats, poultry, contaminated milk, and frozen foods.[10,31] The organism can be part of the bacterial flora of the skin in healthy individuals,[10,15] and the skin frequently becomes a reservoir for *Acinetobacter* in hospitalized patients and the health care staff.[8,10] It occasionally forms part of the normal flora of the oral cavity and the upper respiratory, genital, and lower gastrointestinal tracts.[10,15] Colonization by *Acinetobacter* is particularly common in patients who have undergone a tracheostomy.[63] The organism frequently can be found in the hospital environment, particularly in moist areas, such as in humidifiers, water sinks, and ventilators.[10] Nosocomial outbreaks have been linked to colonized medical equipment such as ventilator tubing and other respiratory equipment,[1,29] intravenous catheters,[10] hygroscopic bandages,[73] gloves,[56] and mattresses.[71]

The frequency of occurrence of nosocomial infections by *Acinetobacter* is not easy to assess because the pathogenic role of this organism often has been underestimated. However, a national surveillance study conducted from 1974 to 1977 identified *Acinetobacter* as a pathogen in 0.76 percent of nosocomial infections.[60] The estimated rate of nosocomial infections caused by this organism was 3.11 per 10,000 patients discharged, and approximately 15 percent of 1372 reported episodes occurred in the pediatric age group.[60] By 1978, this rate increased by 14 percent and accounted for 1 percent of the bacterial isolates associated with nosocomial infections.[15] An unusual seasonal pattern was observed, with most infections occurring in late summer.[15,60] The cause of this increase is unknown. In a national prospective survey of U.S. hospitals from 1995 through 2002, *Acinetobacter* spp. accounted for 1.3 percent of all nosocomial bloodstream infections and was associated with a crude mortality rate of 34 percent.[83] By 2003, the percentage almost doubled to 2.4 percent of nosocomial bloodstream infections from the same surveillance system.[25] When comparing data from 1986 to 2003, *Acinetobacter* spp. were the only gram-negative pathogens associated with a consistently increasing proportion of hospital-acquired pneumonias, as well as surgical site, urinary tract, and bloodstream infections.[25] Data from SENTRY, an international surveillance program that monitors the frequency of occurrence and antimicrobial susceptibility of bacterial pathogens, revealed a significantly greater frequency of *Acinetobacter* infections in Latin America than in all other regions.[24] A higher prevalence rate of *Acinetobacter* infections was noted in patients ranging in age from birth to 10 years.[24] In the pediatric age group, at least 20 outbreaks of invasive nosocomial infections due to *Acinetobacter* have been reported in the past 3 decades[33,34,73]; the vast majority of them were concentrated in neonatal intensive care units (Table 121-1).[34,49,73]

More recently, *Acinetobacter* emerged as a particularly important pathogen in unusual situations such as earthquakes and war zones.[36] This prevalence was illustrated by reports of outbreaks of multidrug-resistant *Acinetobacter* infections associated with the U.S.-Iraq conflict.[68]

PATHOGENESIS

Limited information is available regarding the pathogenesis of *Acinetobacter* infections. The lipopolysaccharide of *Acinetobacter*, a normal constituent of the outer membrane of gram-negative bacteria, is capable of eliciting multiple pathogenic host responses. Strains producing exopolysaccharide have been shown to be more pathogenic than are nonproducers.[36] Nonspecific adherence factors, such as fimbriae, also have been described in *Acinetobacter*.[36] The role of quorum sensing as a regulatory mechanism for autoinduction of multiple virulence factors in *Acinetobacter* is under investigation.[36]

In animal models, *Acinetobacter* can enhance the virulence of other bacteria in mixed infections, perhaps by slime-induced inhibition of neutrophils.[54] Researchers have speculated that the ability of this organism to grow in an acidic pH at lower temperatures may enhance its ability to invade devitalized tissue.[2] The organism also may survive in a dry environment for as long as a week.[16]

CLINICAL MANIFESTATIONS

Acinetobacter can cause suppurative infection of virtually any organ, and the clinical manifestations typically are similar to those seen with other bacterial infections because no unique features are suggestive of *Acinetobacter* infection. The clinical manifestations also may depend on the underlying immune status of compromised hosts.

TABLE 121-1 **Illustrative Nosocomial Clusters of *Acinetobacter* Infection in Pediatric Patients over the Past 3 Decades**

Country	Year	Type of Unit	Infected Children	Colonized Children	Presentation	Mortality (%)	Suspected Source
United Kingdom[49]	1981	NICU	4	0	Meningitis	0	None identified

HCWs, Health care workers; N/A, data not available; NICU, neonatal intensive care unit.

Infections caused by *Acinetobacter* are rare occurrences in normal children[20] and have mostly occurred in tropical areas.

Intracranial Infection

Most cases of *Acinetobacter* meningitis are the result of a penetrating injury or occur after a neurosurgical procedure, although sporadic cases of meningitis have been reported in the absence of these factors. A cluster of eight children in whom *Acinetobacter* meningitis developed after the administration of intrathecal methotrexate was reported.[38] All patients had fever, headache, nausea, and vomiting; and lumbar puncture revealed cerebrospinal fluid (CSF) pleocytosis.

The earlier literature contains several reports of *Acinetobacter* meningitis developing in apparently normal children.[17,18,32,76,80] CSF pleocytosis with a predominance of segmented forms occurred commonly.[18] Because as many as 30 percent of these patients had a petechial rash and gram-negative diplococci on CSF smears, the diagnosis of meningococcal meningitis was made erroneously in most of these cases, thereby leading to a delay in the institution of appropriate therapy and possibly contributing to a mortality rate as high as 27 percent.[18]

Siegman-Igra and associates,[72] in a review of 25 cases of *Acinetobacter* meningitis secondary to invasive procedures that included some children, found that fever, leukocytosis, and neck stiffness, along with other clinical signs of central nervous system (CNS) infection, were common features. The CSF in these patients showed pleocytosis with a predominance of polymorphonuclear leukocytes, elevated protein concentration, and a low glucose level. Most of the infections were associated with indwelling ventriculostomy tubes or a fistula into the CSF space. A case series from Pakistan[65] reported 8 cases of *Acinetobacter* meningitis that occurred over the course of a 4-year period in children who had undergone neurosurgical procedures. Mortality in this series was 25 percent, and the use of intrathecal antibiotics was explored as an adjunctive therapy.[65]

Researchers have suggested that an inherited or acquired complement deficiency may be associated with meningitis caused by *Acinetobacter*[22] because it is seen with *Neisseria meningitidis* and other related species. Treatment of CNS infections caused by *Acinetobacter* requires a minimum of 3 weeks of parenteral antibiotics.

Bacteremia

Acinetobacter bacteremia may occur as an isolated event or may be secondary to a primary infected site, such as the respiratory tract or urinary tract or a wound. Primary bacteremia appears to occur more commonly in immunocompromised neonates, and clinical manifestations can vary from an absence of clinical signs of infection to fulminant septic shock and disseminated intravascular coagulation.[39,67] Thrombocytopenia has been reported to be a prominent feature in these neonates.[35,53,59] Pneumonia has been seen more commonly in early-onset sepsis.[48] Predisposing factors include low birth-weight,[64,67] previous antibiotic therapy,[59,64,67] and the presence of indwelling catheters.[35,47,64]

Acinetobacter bacteremia in children with malignant diseases also has been noted to occur rarely. Fuchs and colleagues[23] reported 29 episodes of sepsis caused by this organism over the course of a 12-year period in an oncology center. All these children were febrile and appeared ill at the time of diagnosis, and a high association of *Acinetobacter* sepsis with the presence of intravascular catheters was noted. Surprisingly, no connection was found with the level of neutropenia.[23]

Respiratory Tract Infections

Because *Acinetobacter* may be a transient colonizer of the pharynx in 7 percent of healthy children[7] and adults[26] and this rate is increased in hospitalized patients, the

relative importance of *Acinetobacter* in comparison with other potential pathogens isolated from sputum is difficult to ascertain. The tracheobronchitis and pneumonia attributed to *Acinetobacter* are mostly nosocomial infections associated with the presence of an endotracheal tube or tracheostomy.[26] Pneumonias frequently are multilobar and occasionally may lead to cavitary destruction or pleural empyema.[26]

Community-acquired pneumonia caused by *A. baumannii* has been reported to occur in adults in the Northern Territory of Australia and other tropical regions.[5] This entity generally is seen in patients with diminished host defenses caused by alcoholism, cigarette smoking, or underlying pulmonary disease and is characterized by the rapid onset of fever, dyspnea, pleuritic chest pain, and purulent sputum. The mortality rate has been as high as 53 to 64 percent.[5] A case of necrotizing pneumonia due to *A. lwoffii* in a previously healthy toddler has been reported.[50]

Miscellaneous Infections

Urinary tract infections occur almost exclusively in patients with indwelling bladder catheters, usually are limited to the bladder, and generally are mild.[26] Burns, as well as traumatic and surgical wounds, frequently become colonized by *Acinetobacter* as a result of the ability of this organism to thrive on compromised tissue and foreign material.[26] Bacteremia may occur as a consequence of this colonization, which is often polymicrobial. *Acinetobacter* is a prominent cause of peritonitis in children undergoing peritoneal dialysis when gram-negative organisms are involved.[81]

Other rare infections caused by *Acinetobacter* that have been reported include suppurative otitis media,[61,76] cellulitis (frequently in association with trauma, a foreign body, or an animal bite),[26,61] synergistic necrotizing fasciitis,[4] native-valve and prosthetic-value endocarditis,[28] septic arthritis,[61] osteomyelitis,[76] and liver abscesses.[26] Ocular infections also have been documented.[45] A case of osteomyelitis occurring after a hamster bite in a child has been described.[46]

DIAGNOSIS

The diagnosis of *Acinetobacter* infection is made by culture of appropriate body fluids or tissue specimens. No serologic or antigen-detection tests are available. A selective medium containing MacConkey agar with cephaloridine has been used to culture skin specimens during investigation of outbreaks[74] because of its ability to inhibit most of the skin flora but not *Acinetobacter*.

Biotyping, phage typing, electrophoretic analysis of isoenzyme and cell wall proteins, plasmid analysis, polymerase chain reaction–based DNA fingerprinting, and restriction endonuclease digestion of DNA have been used for investigation of nosocomial outbreaks.[9] Antibiogram typing no longer is considered an effective method in the investigation of *Acinetobacter* epidemics because the susceptibility pattern may change rapidly within the same outbreak.[9,14]

TREATMENT

As with many other opportunistic gram-negative organisms, treatment of infections caused by *Acinetobacter* spp., particularly those of the *A. baumannii-calcoaceticus* complex,[69,78] have become more complicated by the rapid increase in resistance to the antibiotics used commonly in hospitals. Selection of an antibiotic regimen should be based on in vitro susceptibility testing and ideally should include both a β-lactam antibiotic and an aminoglycoside, which may have synergistic activity[26] and prevent the emergence of resistance.[8]

Species of the *A. baumannii-calcoaceticus* complex have shown decreased susceptibility to ampicillin, broad-spectrum penicillins, cephalosporins, aminoglycosides, and ciprofloxacin.[24,69] Resistance to extended-spectrum cephalosporins may be the result of the presence of cephalosporinases (particularly the chromosomally encoded cephalosporinase AmpC),[12] other broad-spectrum β-lactamases, or changes in the outer-membrane porins and penicillin-binding proteins.[12,55] Resistance to aminoglycosides is mediated by aminoglycoside-modifying enzymes.[78] The carbapenems imipenem and meropenem appear to be the most active agents against *A. baumannii*,[72,78] but reports have found more than 10 percent of such strains to be resistant to these antibiotics in some areas,[24,44] and increasing numbers of nosocomial outbreaks of carbapenem-resistant *Acinetobacter* infections have been reported.[27,77,85] The incidence of carbapenem-resistant *Acinetobacter* strains has been particularly high in Latin America, Africa, Europe, and the Asian Pacific rim region.[11,24,43] Resistance to the carbapenems has been associated with the presence of serine and metallo-β-lactamases (carbapenemases). Of particular concern are the numerous carbapenem-hydrolyzing OXA enzymes that have emerged in *A. baumannii*.[12] Caution should be exercised when using imipenem in high doses in children for the treatment of meningitis (i.e., 100 mg/kg/day) because of an unusually high rate of seizures.[84] Thus, meropenem is recommended for this indication. Doripenem, a newer carbapenem antibiotic, has more potent in vitro activity against *Acinetobacter* species compared with other carbapenems,[21] but its safety and effectiveness in pediatric patients have not been established. On the other hand, ertapenem has poor in vitro activity against *Acinetobacter*[41] and should not be used for the treatment of these infections. Combinations of a β-lactam antibiotic with a β-lactamase inhibitor, such as ampicillin-sulbactam, piperacillin-tazobactam, or ticarcillin-clavulanate, have been used for infections caused by carbapenem-resistant strains.[77,85]

The fluoroquinolones, in particular ciprofloxacin, have been used successfully to treat infections caused by multidrug-resistant *Acinetobacter* in children[48,58] and adults. Although ciprofloxacin has been approved for the treatment of complicated urinary tract infections in children and levofloxacin for postexposure treatment of inhalation anthrax in the pediatric age group, the other systemic fluoroquinolones are not approved for use in children younger than 16 years of age because of the theoretic concern for damage to growth cartilage. Of the

quinolones, gatifloxacin exhibits the best in vitro activity against *A. baumannii*, followed by levofloxacin and trovafloxacin.[30] Although 76 to 86 percent of sporadic isolates of *A. baumannii* are susceptible to the fluoroquinolones, only 32 to 55 percent of outbreak-related strains remain susceptible to this antibiotic class.[30] Topoisomerase mutations in both *gyrA* and *parC* have been identified in quinolone-resistant *A. baumannii*.[12] In some cases, the polymyxin drugs polymyxin B and colistin are the only therapeutic options for the treatment of multidrug-resistant *Acinetobacter* infection.[27,40] Efflux pumps capable of conferring resistance to multiple antibiotic classes have been identified in *Acinetobacter* spp.[12,43,62]

Tigecycline is the first member of the glycylcycline antimicrobial class to gain approval in the United States. Because this agent demonstrates in vitro activity against multidrug-resistant strains of *A. baumannii*, its potential use as an alternative therapy for severe infections caused by this organism is being investigated.[62] Data regarding the use of this agent in pediatric patients are lacking. The development of resistance to tigecycline among clinical isolates of *Acinetobacter* has been documented and appears to be increasing in some regions.[3,43]

Imipenem, meropenem, amikacin, ciprofloxacin, ceftazidime, and ceftriaxone have exhibited good in vitro activity against isolates identified as species other than the *A. baumannii-calcoaceticus* complex.[69] In addition to antimicrobial therapy, prompt drainage of focal suppurative sites and removal of infected indwelling catheters are essential. Intraventricular administration of amikacin, polymixin B, or colistin has been used in the treatment of CNS infections caused by this organism.[65,82] Similarly, the use of adjunctive aerosolized therapy with colistin or tobramycin has been explored in adults with pulmonary infections.[6]

PROGNOSIS

Because *Acinetobacter* strains often are resistant to the antibiotics used commonly, prompt recognition of the specific cause and institution of effective antibiotic therapy are critical to achieving a successful outcome. The reported mortality rate in a series of pediatric patients ranged from 0 percent to more than 50 percent (see Table 121-1), and the outcome appeared to correlate more closely with the underlying condition than with other factors such as polymicrobial bacteremia.[75] In a series of 58 infections caused by this organism that occurred over the course of a 2-year period from 1973 through 1974 at the Massachusetts General Hospital in Boston, the mortality rate was 23 percent.[26] A 1999 prospective study in the Slovak Republic revealed that the case-fatality rate for 157 episodes of *A. baumannii* bacteremia was significantly higher in adults than in children (34% vs. 12%).[39] A recent systematic review that included a total of 469 children from 51 outbreaks and case series of invasive *Acinetobacter* infections revealed an attributable mortality of 14.5 percent.[34]

The nosocomial acquisition of multiresistant *A. baumannii-calcoaceticus* complex has been associated with high mortality rates and prolonged hospitalization in adult patients in intensive care units,[42,66] in contrast to the more benign clinical outcome usually seen with other species of *Acinetobacter*.[70]

PREVENTION

Nosocomial acquisition of *Acinetobacter* by high-risk compromised hosts can be prevented by placing emphasis on the control measures routinely used for endemic infections, such as careful hand washing by personnel, limitation of the frequency and duration of use of devices, proper isolation of colonized and infected patients, application of strict techniques for invasive procedures, restricted use of antibiotics, and implementation of antibiotic stewardship programs.[16,42,43,73]

CHAPTER 122

Achromobacter (Alcaligenes)

Randall G. Fisher

Organisms of the genus *Achromobacter* are gram-negative bacilli that live in aqueous environments. Originally considered commensals, they increasingly are recognized as important, although rare, hospital pathogens. *Achromobacter* can be especially problematic in immunocompromised patients and in neonates, in whom infection can be life-threatening. These organisms have been isolated from such diverse clinical specimens as sputum, urine, feces, blood, cerebrospinal fluid, cornea, and peritoneal and pleural fluids.

BACTERIOLOGY

Achromobacter spp. are gram-negative, motile, indole-negative, obligate aerobes that are oxidase- and catalase-positive. They are considered to be nonfermenters because of their extremely limited action on carbohydrates. Most ferment xylose, and some ferment glucose. All reduce nitrate to nitrite. They are urease-, lysine-, and ornithine-negative. They grow well on both blood and MacConkey agar and produce colonies that are smooth and glistening and have a distinct edge. *Achromobacter* spp. alkalinize organic salts and amides, a property that led to the name *Alcaligenes*, which means *alkali producing*. *Alcaligenes faecalis* has a distinct, sweet odor that has been described as resembling that of green apples.[29]

Bacteriologically, these bacilli may be confused with other nonfermenting gram-negative organisms, especially *Pseudomonas* spp. Morphologically, however, they can be distinguished easily from pseudomonads by the presence of peritrichous flagella: *Pseudomonas* spp. have polar flagella.[25]

The taxonomy of these organisms is confusing and undergoes frequent changes. They were classified as *Achromobacter* spp., then reclassified as *Alcaligenes*, and have been reassigned the name *Achromobacter*. The genera *Achromobacter* and *Alcaligenes* are closely related and comprise many species, but clinically important ones are as follows: (1) *Achromobacter xylosoxidans*, which has two subspecies: *xylosoxidans* and *dentrificans*, the former of which is the most common cause of clinically recognizable infection; (2) *A. faecalis*, which is a less common pathogen but has a distinct antimicrobial susceptibility pattern[6]; (3) and *Achromobacter piechaudii*, which has been isolated from clinical specimens[42] but is of doubtful significance. In the discussion that follows, the abbreviation *A. xylosoxidans* refers to *Achromobacter xylosoxidans* subspecies *xylosoxidans*.

EPIDEMIOLOGY

Like *Pseudomonas* spp., *Achromobacter* are water organisms and prefer aqueous environments and moist soil. They do not survive long on porous surfaces or fomites or if they become desiccated.[46] They also may be part of the normal flora of the ear and of the gastrointestinal and respiratory tracts of some people. These organisms establish a niche within the hospital environment and have been recovered from ventilators, humidifiers, "sterile" saline, intravenous fluids, and irrigation and dialysis solutions. *Achromobacter* spp. also have been recovered from infant formula,[18] children's soap bubbles,[38] well water,[52] and swimming pools.[27] Organisms also survive many disinfectants and have been cultured from chlorhexidine,[49] 1 percent eosin,[7] and alcohol- or quaternary amine–containing compounds.[46,49] Shigeta and associates[49] reported an outbreak of *A. xylosoxidans* ventriculitis secondary to contaminated chlorhexidine used on a surgical ward. Foley and colleagues[21] reported an outbreak accompanied by deaths in a neonatal intensive care unit secondary to contamination of saline used as an eyewash. Boukadida and coworkers[7] reported a neonatal death caused by meningitis contracted by dissemination after treatment of a diaper rash with 1 percent eosin. An outbreak of 37 cases (with two fatalities) that was caused by bacterial contamination of deionized water in a hemodialysis system was described by Reverdy and associates.[43] Surgical wound infection also has occurred in which infection was suspected to be secondary to contaminated irrigation fluids used in surgery.[59] One outbreak of four cases in a hemodialysis unit was linked to an atomizer of 2.5 percent chlorhexidine used to disinfect the skin.[55] Three kinds of pseudo-outbreaks have been described: in one, seven patients in a pediatric hospital were infected with *A. xylosoxidans*, but restriction fragment-length polymorphism analysis proved they all were genetically unrelated[5]; in another, *A. xylosoxidans* was isolated from three different clinical specimens but was later proved to be a contaminant of the saline used in their processing[24]; in a third, blood cultures were positive when drawn on the night shift because the nurses were cleaning the top of the blood culture bottles with a contaminated disinfectant.[51]

Studies have documented that *A. xylosoxidans* colonization of patients with cystic fibrosis is on the rise. In one large study, *A. xylosoxidans* was isolated from the sputum culture of 52/595 patients (8.7%).[8] In other studies, isolates of *A. xylosoxidans* at a single cystic fibrosis center

were not genetically related, a finding implying no common source of infection and little or no patient-to-patient spread within the center.[16,58] However, colonization of multiple patients with identical strains also is well documented.[44] Colonization rates as high as 17.6 percent have been reported; many of these patients were shown to be chronically colonized.[31] Most investigators report no significant changes in forced expiratory volume in 1 second (FEV_1) or growth parameters in *A. xylosoxidans*–colonized patients.[31] Environmental cultures at one cystic fibrosis center were positive for *A. xylosoxidans* only 0.8 percent of the time, whereas 22.8 percent of such cultures were positive for *Pseudomonas aeruginosa*.[20]

PATHOPHYSIOLOGY

Achromobacter spp. are weakly virulent bacteria. Medical care commonly provides the conduit through which organisms are introduced into their host, by way of indwelling catheters, endotracheal tubes, and so forth. The bacteria may take advantage of a weakened immune system and disseminate, causing sepsis, meningitis, and death. Preterm or term infants who are small for gestational age are at particular risk for acquiring such severe *Achromobacter* infections.[21] Although most neonatal infections are considered to be nosocomial, vertical transmission from mother to baby may occur.[25] An increased incidence of infection has been reported for patients with neoplasms[32] and those receiving long-term steroid therapy.[28] Sporadic cases of *Achromobacter* infection in patients with idiopathic immunoglobulin (Ig)M deficiency,[17] Waldenström macroglobulinemia,[53] and systemic lupus erythematosus have been reported.[45] My colleagues and I have seen one boy with hyper-IgM syndrome in whom 14 separate episodes of *Achromobacter* bacteremia occurred; an exhaustive environmental search for a source was fruitless. The source was eventually proved to be deep infection of a cervical lymph node, and the episodes ceased when the node was removed.[60] *Achromobacter* infections occur in patients with acquired immunodeficiency syndrome (AIDS),[9,23] but whether this syndrome is an independent risk factor for infection is unclear.

In one study, patients with cystic fibrosis and colonized with *A. xylosoxidans* tended to be older (mean age, 20 years) and at baseline had worse lung function than did noncolonized controls; however, over the course of the study, the rate of decline of lung function did not differ between cases and controls.[11] In a second similar case-control study, lung function decline and growth parameters generally were not affected by colonization; however, a subset of patients had rapidly increasing antibody titers against *A. xylosoxidans*, and this group did experience more accelerated decline.[44]

In unusual circumstances, patients with neither overt underlying disease nor obvious immune deficiency will develop infection with *Achromobacter* spp. Most of these cases involve penetrating trauma. One case of corneal infection complicating epidemic keratoconjunctivitis in a normal host has been described.[39] Eye infections, including conjunctivitis and keratitis, also have occurred in patients who wear contact lenses; the organism was also recovered from contact lens cases and solutions.[30,35] Severe infection requiring corneal transplantation occurred two months after LASIK.[34]

CLINICAL MANIFESTATIONS

Signs of sepsis or meningitis caused by *A. xylosoxidans* in the newborn are difficult to differentiate from other causes of bacterial sepsis. However, some babies may develop a distinctive rash in association with this infection, in which 1- to 2-cm, sharply demarcated red patches appear, especially in the head and neck region. This rash was noted in 29/33 newborns with *A. xylosoxidans* infection reported by Doxiadis and associates in 1960[14] and was seen again in a case reported in 1993.[7] *A. xylosoxidans* sepsis and meningitis tend to manifest later in life than do infections with the usual vertically acquired pathogens and may have a more insidious onset.[36] In some cases, cerebrospinal fluid profiles may resemble those usually associated with viral meningitis, with white blood cell counts in the hundreds, and with monocytic predominance.[47] Neonatal *Achromobacter* sepsis or meningitis has an extremely poor prognosis; one series noted a mortality rate that approached 75 percent, and 36 percent of survivors had severe neurologic deficits.[21] The incidence of intracranial hemorrhage also was high.

Three large series of bloodstream infections with *A. xylosoxidans* all revealed a similar story; most cases are nosocomial, most patients have an underlying malignant disease, many are neutropenic or receiving high-dose steroids, and many have indwelling vascular catheters.[2,22,48] Polymicrobial bacteremia was not rare in these series. Mortality rates ranged from 15[22] to 48 percent.[48] Risk factors for mortality were age older than 65 years at diagnosis, neutropenia, nosocomial acquisition, and polymicrobial bacteremia. An earlier review of reported cases revealed that the case-fatality rate was lowest in patients with catheter-associated bacteremia and highest (65%) in those with pneumonia, meningitis, or endocarditis.[15]

An outbreak of urinary tract infection was traced to ultrasound gel used in transrectal ultrasound-guided prostate biopsies.[40] Urinary tract infections are generally seen in elderly patients with underlying malignancies or urologic abnormalities.[54]

One child developed osteomyelitis caused by *A. xylosoxidans* after stepping on a nail through old sneakers (a clinical situation classically associated with *Pseudomonas* infection)[26,27]; another developed *Achromobacter* infection as a consequence of a gunshot wound.[10] In the setting of a patient with an artificial heart valve, *A. xylosoxidans* endocarditis has been described.[41] In another case, endocarditis was associated with an abandoned pacemaker lead.[1] A case series of liver abscesses included three patients from whom *A. xylosoxidans* was isolated, all of whom shared a clinical pattern—history of cholecystectomy, "coral-like" multilobulated appearance on computed tomography, and epithelioid granulomas at the periphery of the abscesses.[3] *A. xylosoxidans* infection in older patients usually is not suspected on clinical grounds but rather in the context of a common-source outbreak

or because of microbiologic clues. *A. faecalis* infection is less common and usually is part of a polymicrobial process.

DIAGNOSIS AND TREATMENT

Generally, the diagnosis of *Achromobacter* infections rests on recovery of the organism from clinical samples, although newer methods sometimes have been employed. In one case of culture-negative endophthalmitis, fluid obtained from the anterior chamber was subjected to polymerase chain reaction (PCR) using a 16S rDNA primer set, finding a 214 base pair sequence from *A. xylosoxidans*.[57] These organisms often are mistaken for pseudomonads, and the clinician should suspect *A. xylosoxidans* when the laboratory reports an organism as a *Pseudomonas* spp. that is resistant to all aminoglycosides.[46] Key differentiation features include the antibiogram and the morphology of the organism, with its distinctive peritrichous flagella. The organism can be identified in the sputum of cystic fibrosis patients using a PCR for the bla(OXA-114-like) gene, which is constitutive in *A. xylosoxidans*.[56] Matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF) also has been used to identify nonfermenting gram-negative rods in cystic fibrosis sputum with great accuracy, correctly identifying 549/559 strains.[13]

Achromobacter spp. typically are resistant to a large number of antibiotics, including ampicillin, aztreonam, aminoglycosides, first- and second-generation cephalosporins, tetracyclines, and rifampin. They variably are resistant to chloramphenicol, fluoroquinolones, macrolides, ureidopenicillins, and β-lactamase combination drugs.[6] *Achromobacter* spp. have been shown to produce β-lactamases, some of which are chromosomal, constitutive, and inducible[12] and some of which are on plasmids.[33] Some isolates overproduce β-lactamase,[12] which stoichiometrically can render β-lactamase inhibitors useless. In addition, their porins are small, thus rendering antibiotic entry difficult. More recently, a multidrug efflux pump of the RND-type has been described.[4] Although there is no antibiotic to which all isolates have been shown to be sensitive,[41] most are sensitive in vitro to trimethoprim-sulfamethoxazole, piperacillin-tazobactam, imipenem, ceftazidime, and cefoperazone. Imipenem-resistant strains also have been discovered. These strains produced VIM-2, OXA-30, and a chromosomal AmpC β-lactamase.[50] Two case reports describe treatment failures of ceftazidime[37] and piperacillin[12] in clinical isolates that were sensitive at the time of isolation but developed resistance during the course of therapy.

Because resistance patterns vary across isolates, the combination of a third-generation cephalosporin, piperacillin (or piperacillin-tazobactam), or imipenem with trimethoprim-sulfamethoxazole is reasonable empirical therapy for suspected *Achromobacter* infection, pending susceptibility results. In general, in vitro susceptibilities seem to correlate well with in vivo results,[32] but the risk for inducible resistance to β-lactam antibiotics should be acknowledged. One report described synergy in microbial killing with an aminoglycoside, even though the isolate was resistant to the same aminoglycoside when it was tested alone.[9] This phenomenon was confirmed by two-disk Kirby-Bauer approximation methods using 11 clinical blood culture isolates; all were resistant to gentamicin, but 10/11 were inhibited synergistically when gentamicin was added to ticarcillin-clavulanate, and 9/11 displayed synergy when gentamicin was added to piperacillin or ceftazidime.[15]

Removal of infected catheters may speed recovery, although some patients have been treated successfully through indwelling lines.[9] Because of a high recurrence rate, experts in the care of patients with renal failure treated with continuous ambulatory peritoneal dialysis recommend removal of peritoneal catheters in patients who develop peritonitis with *A. xylosoxidans*.[19]

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 123

Eikenella corrodens

Randall G. Fisher

Eikenella corrodens is a facultatively anaerobic, fastidious gram-negative rod that is part of the normal flora of the mouth and the gastrointestinal and genitourinary tracts. Long regarded as a commensal, its pathogenicity no longer is in doubt. It frequently is a pathogen of periodontitis in both adults and children and is a common isolate from wounds that have been contaminated by oral secretions. It also has been recovered from pleuropulmonary infections, central nervous system infections, orbital cellulitis, peritonsillar abscesses, abdominal infections, osteomyelitis, and bloodstream infections, including endocarditis.

BACTERIOLOGY

In 1948, Hendriksen[18] described the organism and called it the "corroding bacillus" because it pitted the agar. It was characterized more fully in 1958 by Eiken,[10] who named it *Bacteroides corrodens*. In 1972, Jackson and Goodman[19] separated two species of corroding bacteria; the strict anaerobe kept the name *B. corrodens* (now called *Bacteroides ureolyticus*), and the facultative anaerobe was classified as *Eikenella*. It is a small, straight, nonmotile gram-negative rod that occasionally is coccobacillary. It is oxidase positive and catalase negative. Most strains are positive for lysine and ornithine decarboxylase. The organism is nonfermentative, reduces nitrate to nitrite, and is negative for urease and indole. *E. corrodens* cell surface components vary from isolate to isolate; these differences probably relate to virulence.[6]

E. corrodens will grow either aerobically or anaerobically, but its growth is not rapid. Growth can be enhanced by 3 to 10 percent carbon dioxide. It grows on blood or chocolate agar but poorly or not at all on MacConkey agar. Selective medium, which contains clindamycin, may increase the yield. Colonies are small and grayish. They look slightly yellow when they are old. Although *E. corrodens* is nonhemolytic, a faint green appearance may be seen on blood agar. Approximately 50 percent will produce the characteristic pitting. They elaborate an odor that resembles that of bleach or hypochlorite.[19]

E. corrodens is a member of the so-called HACEK family of organisms, which have the following in common: slow growth, a requirement for carbon dioxide, and a predilection for infecting heart valves. The other members of the family are *Aggregatibacter*[33] (formerly *Haemophilus*) *aphrophilus*, *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans*, *Cardiobacterium hominis*, and *Kingella kingae*.

EPIDEMIOLOGY

Infection with *E. corrodens* occurs when mucosal or skin barriers are disrupted and the organism gains access to deeper tissues. Puncture of the skin with forks[35] or toothpicks[41] may result in deep-seated infections. One case of vertebral osteomyelitis that occurred after a woman accidentally inoculated the organism into the paravertebral space by penetration of a fish bone through the posterior pharynx has been reported.[30] In a similar case, a fish bone stuck in the throat for 2 months eventually led to a spinal epidural abscess.[23] Infection commonly occurs after clenched-fist injury as a result of fistfighting.[14] Hand infections in children are more likely to be secondary to digital biting or sucking.[16] Intravenous drug abusers are at risk for injection-site and soft tissue abscesses,[15] bacteremia, and endocarditis.[9,34] Elderly persons and patients with advanced carcinomas are the other high-risk groups. However, children are at particularly high risk for serious *E. corrodens* infections.[40] Reports of thyroid abscesses[7,49] and purulent thyroiditis[39] all have been in children. In one review,[25] more than 20 percent of *E. corrodens* pleuropulmonary infections occurred in children younger than 14 years of age and more than 50 percent of abdominal infections were reported in patients younger than 25 years of age.[8] *E. corrodens* orbital cellulitis,[17] empyema,[46] peritonsillar abscess,[27] paronychia,[1] and osteomyelitis[37,43] have been observed in children. A review of 54 cases of *E. corrodens* infection in children and adolescents revealed that 41 percent of pediatric infections occurred in the head and neck. The most common single site was the thyroid gland.[35]

PATHOPHYSIOLOGY

E. corrodens infections often are polymicrobial[47] and may include other anaerobes or gram-negative rods. However, *E. corrodens* is accompanied most frequently by recovery of α-hemolytic streptococci. In most reports, the streptococci were not speciated further but Jacobs and associates[21] made a case for the *Streptococcus anginosus* group because of similarities between the two organisms (i.e., both are found in the mouth and gastrointestinal tract, both produce local suppurative infection, and both thrive in carbon dioxide–rich, oxygen-poor environments). Brooks and colleagues[4] also reported synergy of the two organisms in a rabbit model of skin infection. In vitro studies of *E. corrodens* cocultivated with members of the *S. anginosus* group showed that a significant degree of

coaggregation occurs. Additionally, exponential growth of *Streptococcus constellatus* and *Streptococcus intermedius* occurs 6 hours into incubation when these species are grown in the presence of *E. corrodens;* in its absence, exponential growth does not occur until 25 hours after inoculation.[51]

The possible role of *E. corrodens* in periodontitis has not been delineated precisely. However, soluble products of *E. corrodens* induce gene expression and protein production of vascular endothelial growth factor and cause phosphorylation of mitogen-activated protein kinase in vitro, a process that leads to increased production of interleukin-8 and adhesion molecules.[52] This cascade of inflammatory responses could promote chronic periodontitis.

E. corrodens has a propensity toward formation of an abscess in any location, whether alone or in concert with other organisms. Such formation is a hallmark of central nervous system infection.[3] Of intra-abdominal infections reported by Danziger and associates,[8] 15 of 19 patients had abscesses. In two cases of orbital cellulitis reported by Hemady and coworkers,[17] both patients had subperiosteal abscesses. Deep or superficial skin abscesses reported in drug addicts[15] or in clenched-fist injury from fistfighting[14] often recur, even after presumed adequate drainage.[38]

CLINICAL MANIFESTATIONS

Infections with *E. corrodens* are indolent. The time from inoculation to onset of symptoms generally is 1 week or longer.[4] Many cases show initial improvement with treatment but relapse days later, even with appropriate therapy.[16,27,36,40] The head and neck are the most common sites of infection at all ages.[35]

Infection of periodontal sites may be associated with rapid progression and bone resorption thought to be secondary to surface-associated materials of *E. corrodens* and other organisms of periodontitis.[31] Craniofacial and neck infections tend to have prolonged morbidity; many require repeated drainage procedures and long courses of antimicrobial agents.[40] Central nervous system infections often are preceded by sinus infections but also have been seen in children with congenital heart disease.[2,48]

Pleuropulmonary infections are marked by fever, cough, and chest pain. Necrotizing pneumonia with multiple abscesses sometimes is seen. Effusions or empyema are noted in 30 percent, and cavitation is seen in 8 percent. Children with a predisposition toward aspiration may be at higher risk.[25] In one case, a bedridden 16-year-old girl developed a bronchopleural-cutaneous fistula complicating necrotizing pneumonia with empyema.[50]

Endocarditis is associated with large, friable vegetations and frequent emboli and often requires valve replacement.[11] Intravenous drug use has been implicated in approximately half of reported cases.

Abdominal *E. corrodens* infections are seen most commonly as complications of ruptured appendicitis but also have been associated with abdominal trauma and surgery. The clinical course is protracted.[8]

Chorioamnionitis leading to premature delivery has been documented.[12,22] In one case, the infection precipitated the birth of twins at 23 weeks' gestation and led to the demise of one twin.[24,26,45]

Soft tissue infections tend to be severe. Many require wide débridement and skin grafting. Infection of underlying joints, tendons, or bones is not infrequent and can be necrotizing and even lead to amputation.[38]

DIAGNOSIS

Definitive diagnosis rests on recovery of *E. corrodens* in culture, which can be a difficult task because of the organism's slow growth. *Eikenella* tends to be overgrown by hardier species when it is part of a polymicrobial process and may be missed, especially if the isolate does not pit the agar. All the HACEK organisms can pit agar,[5] although not with the regularity of *E. corrodens.*

Many bacteriology laboratories have difficulty identifying and separating catalase-negative, oxidase-positive, gram-negative rods. Not surprisingly, one report noted that of 100 isolates of *E. corrodens* identified by the National Collection of Type Cultures, only 21 were sent in as probable *E. corrodens.*[5] Organisms that *E. corrodens* may be mistaken for include the other HACEK organisms, *Aggregatibacter* (formerly *Haemophilus*) *paraphrophilus*, *Moraxella atlantae*, and *Actinobacillus ureae.*

TREATMENT

E. corrodens has a very unusual antimicrobial susceptibility pattern: although most isolates are sensitive to penicillin and ampicillin, they are resistant to semisynthetic penicillins, such as methicillin and nafcillin.[44] Additionally, these organisms uniformly are resistant to clindamycin and metronidazole,[20] drugs commonly used to treat anaerobic infections. They also variably are resistant to aminoglycosides.

Most isolates are sensitive to piperacillin, second- and third-generation cephalosporins, carbapenems, second- and third-generation fluoroquinolones, and tetracycline. In one report, all of 31 *Eikenella* isolates derived from normal oral flora were sensitive to azithromycin in vitro.[32] Although penicillin often is cited as the drug of choice, some strains produce β-lactamases. One report associated the β-lactamase with a transposon[29] and another with a plasmid[42]; one report found a chromosomal enzyme that was not inducible.[28] In addition, there are reports of intermediate resistance to penicillin, even in isolates that do not produce a β-lactamase.[13]

Incision and drainage of abscesses and débridement of necrotic tissue are essential to recovery from these infections. Therapy should be prolonged after patients apparently have recovered because early cessation of antibiotic therapy tends to be associated with relapse. If patients continue to have fever or other signs of infection days after appropriate therapy has been started, obtaining

more images of the infected area may be prudent to detect early reaccumulation of purulence.

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 124

Elizabethkingia and *Chryseobacterium* Species

Randall G. Fisher

Members of the genus *Chryseobacterium* (formerly *Flavobacterium*) seldom are associated with human infection. Most disease occurs after exposure to a contaminated environmental source. In 1944, Shulmann and Johnson[52] reported a case of meningitis caused by a previously unidentified, gram-negative bacillus isolated from a 9-day-old premature infant. The term *Flavobacterium meningosepticum* was proposed for this organism by King[31] in 1959, based on her studies of bacterial isolates associated primarily with neonatal meningitis and septicemia. Although neonatal meningitis is the most common manifestation of human disease caused by this genus,[15,58] sepsis,[14,23,44,55] endocarditis, pneumonia,[46] septic arthritis with penetrating trauma or prosthesis,[22,32] and skin infection[19] (including one case of necrotizing fasciitis)[33] occur in individuals beyond the newborn period.[3]

BACTERIOLOGY

The taxonomy of these organisms is confusing because of frequent changes. All but one of the clinically relevant species of the original genus *Flavobacterium* were reclassified to the new genus *Chryseobacterium* in 1994.[62] Phylogenetic analysis based on 16S rRNA sequencing demonstrated that the organisms formerly classified as *Chryseobacterium meningosepticum* and *Chryseobacterium miricola* represent a separate lineage. Researchers proposed that these two organisms be moved to a new genus, named *Elizabethkingia* after the microbiologist who first described them.[30] The former *Flavobacterium odoratum*, rarely responsible for human disease, has been divided into two species (*odoratus* and *odoratimimus*) reclassified as members of the genus *Myroides*.[61] *Chryseobacterium indologenes* is the species isolated most frequently from human specimens,[28] but it usually is not associated with significant disease. Therefore, this chapter focuses mainly on *Elizabethkingia meningosepticum*, which can cause severe infections, especially in newborns. These organisms are long, thin, catalase-positive, gram-negative rods with slightly swollen ends; they are nonmotile, oxidase-positive, weakly fermentative, and proteolytic and grow on solid agar as 1- to 2-mm, convex, glistening colonies of buttery consistency.[31] Yellow pigmentation is seen occasionally. Colonies do not demonstrate hemolysis on blood agar but may produce a lavender-green color in the surrounding media as a result of extensive proteolytic enzyme activity. *Elizabethkingia* is unable to grow on *Salmonella-Shigella* agar or Simmons citrate and lacks motility. These characteristics distinguish *Elizabethkingia* from *Pseudomonas*, with which it often is confused.[15] Similarly, use of glucose in an open tube of oxidation-fermentation media distinguishes *Elizabethkingia* from *Achromobacter faecalis*.[15] The clinically relevant species *E. meningosepticum* (also referred to interchangeably in the current literature by its old name *Chryseobacterium meningosepticum* and in the older literature as *Flavobacterium meningosepticum*) and *Flavobacterium IIB* (renamed *Flavobacterium balustinum*) are differentiated by the former's consistent liquefaction of gelatin and early use of

mannitol and maltose and the latter's lack of these abilities.[31] *Myroides odoratus* and *Myroides odoratimimus (F. odoratum)*, which have been identified most commonly as saprophytes in skin wounds,[26] characteristically are nonsaccharolytic and produce a fruity odor when they are grown on standard media.

EPIDEMIOLOGY

Elizabethkingia spp. and chryseobacteria are distributed widely as saprophytes in fresh and salt water, as well as in the soil. *E. meningosepticum* has been identified as a pathogen in birds.[60] In hospitals, these organisms have been found to be ubiquitous colonizers of the patient's environment and have been isolated from flower vases,[57] ice machines,[55] vials of intravenous drugs,[44] and nebulizers.[16] In addition, tap water,[16] eyewashes,[47] tube feedings,[16] sink traps,[8] and hand cultures of hospital personnel[16] have yielded this organism. In some instances, these reservoirs have been implicated in nosocomial outbreaks of patient colonization and invasive disease.

Neonatal infection caused by *E. meningosepticum* has been reported frequently in the literature, often in association with nursery epidemics.[2,7,49] As with other neonatal pathogens, infants who are premature and small for gestational age seem to be at particular risk for infection. More than 50 percent of infected infants weigh less than 2500 g. Almost all cases occur within 3 weeks of birth, and more than 50 percent of these infants manifest illness before they are 7 days old.[15]

Nosocomial epidemics have occurred sporadically since the nursery outbreak reported by Brody and colleagues in 1958.[2,5,7,8] Cabrera and Davis[8] reported such an outbreak in detail in 1960. During a 3-month period, the bacteria were isolated from a total of 44 infants, of whom 14 had overt infection. Most colonized infants had organisms isolated from the nasopharynx. The only reservoir of infectious bacteria discovered was a faulty sink trap, beneath which cleaning materials for the nursery were stored. Repair of the defective trap and thorough cleansing and repainting of the nursery coincided with termination of the epidemic. In one situation, respiratory tract colonization developed in four premature neonates, but none of them developed disease; routine infection control measures ensured that no further infants were colonized.[40]

Nursery outbreaks of *E. meningosepticum* have been traced to saline used to flush infants' eyes after administration of silver nitrate,[47] and organisms have been recovered from washbasins, sinks, disinfectants, and suction devices in other epidemics.[8] Colonization of patients in a surgical intensive care unit was associated with tap water, sinks, ice machines, and washbasins yielding the bacteria.[16] Ribotyping and random amplified polymorphic DNA fingerprinting (RAPD) offer promise for more precise characterization of epidemics.[12,13] Use of these techniques has demonstrated, in some cases, that isolates in what appears to be an outbreak may be unrelated. In one case, isolates from the surrounding environment were also unrelated to the types found in the patients.[64]

PATHOPHYSIOLOGY

Elizabethkingia spp. and *Chryseobacterium* spp. generally are of low virulence. Rabbits administered 1-mL intravenous infections of 24-hour-old broth cultures demonstrated no mortality or morbidity; death rates were less than 30 percent in mice inoculated intracerebrally with "barely turbid" preparations.[31]

Most cases of invasive human disease are thought to be caused by environmental contamination with high numbers of *E. meningosepticum*, with spread to the compromised newborn or debilitated older patient. Some neonatal infections may be caused by colonization of the infant during passage through the birth canal of a colonized mother.[13] Intrapartum infection is supported by occurrence of symptoms as early as 10 hours after birth.[15] However, only 0.3 percent of genital swabs submitted from patients with suspected venereal disease yielded the organism.[43] Continuing reports of *E. meningosepticum* as a cause of neonatal infection in developing countries have been speculated to be related to use of contaminated groundwater for bathing of newborn infants and feminine genital hygiene.[15] The propensity for this organism to produce meningitis in the newborn is not understood, but infection may occur in association with heavy nasopharyngeal colonization, leading to subsequent bacteremia and seeding of the meninges.

Cases in older children have been related to insulin-dependent diabetes mellitus,[9] thalassemia major with splenectomy,[45] and oncologic disease with indwelling catheters.[42] Peritonitis in patients undergoing continuous ambulatory peritoneal dialysis, including a case series of 30 patients, also has been reported.[46]

In older individuals, *E. meningosepticum* and chryseobacteria primarily play the role of opportunists.[39] Heavy nosocomial colonization combined with a blunted immune response probably accounts for the immunocompromised patient's poor capacity to handle this otherwise noninvasive bacterium.

CLINICAL MANIFESTATIONS

Neonatal sepsis and meningitis caused by *E. meningosepticum* share signs and symptoms in common with other forms of neonatal bacterial infection. However, the development of meningitis may be insidious, and several days of illness often pass before its presentation[15,49]; this factor is consistent with the low virulence of *E. meningosepticum* in contrast to other agents of neonatal sepsis. Prognosis is extremely poor, and mortality rates may exceed 60 percent.[34] Fifty percent of survivors develop significant neurologic complications, often in association with hydrocephalus.[35]

These organisms are uncommon pathogens in adults, and childhood disease occurring beyond the newborn period is extremely rare. Among the 24 initial isolates of *E. meningosepticum* identified by King,[31] organisms were identified in a throat culture from an adult patient and in cerebrospinal fluid (CSF) from an 8-month-old infant. Bacteria formerly classified as *Flavobacterium IIB*

(now known as *F. balustinum*) were isolated from the blood and CSF of several adult patients without clinical information.[27] Since their initial identification in 1959, these agents have been implicated as causes of meningitis,[39,49] postoperative bacteremia,[3,43] bacterial endocarditis,[65] pneumonia,[56,57] catheter-associated infection, septic arthritis, and skin infection.[19] *E. meningosepticum* is the clinically relevant species most commonly isolated, but *C. balustinum*, *M. odoratus*, and *M. odoratimimus (F. odoratum)* and other *Chryseobacterium* spp. have been implicated in human disease. *Elizabethkingia* and *Chryseobacterium* spp. accounted for 0.25 percent of infections in a large consecutive series of patients with human immunodeficiency virus infection. Risk factors included low CD4 counts and leukopenia.[38]

E. meningosepticum meningitis beyond the neonatal period typically occurs in immunocompromised patients. Adults with preexisting leukemia,[49] glomerulonephritis,[39] and squamous cell carcinoma[23] have been described as having meningitis caused by this organism. In a 56-year-old woman, meningitis with *E. meningosepticum* developed after she underwent transsphenoidal hypophysectomy[10]; in an 8-month-old male child with preceding severe neurologic damage, meningitis developed with bacteria designated by the Centers for Disease Control and Prevention as *Flavobacterium*-like organisms (IIE). In a 6-week-old infant, *E. meningosepticum* bacteremia and meningitis developed in association with a strangulated hernia.[15]

Elizabethkingia and *Chryseobacterium* spp. were isolated frequently from tracheal aspirates of patients in intensive care during a 70-month observation period; yet during that time, none of more than 2000 critically ill patients developed pneumonia attributable to these microbes.[16] However, true respiratory tract infection was identified in an intubated pediatric patient and in adults receiving aerosolized medications.[6,57]

Sporadic cases of bacteremia have been reported in adult patients.[23,36] Two reviews of adult bacteremia in Taiwan have been published. The largest of these included 118 patients at a single center over a 7-year period. The incidence of *E. meningosepticum* bacteremia increased from 7.5/100,000 admissions in 1999 to 35.6/100,000 in 2006. The vast majority of these infections were nosocomial, and 60 percent were acquired in intensive care units. Approximately a third of the patients had malignancy, and a fourth suffered from diabetes mellitus. The 14-day mortality rate was 23.4 percent. The main risk factor for mortality was acquisition of infection in an intensive care unit setting (odds ratio, 4.23). Rapid institution of appropriate antibiotic therapy reduced mortality.[29] Infection in immunocompromised patients can occur as a complication of relatively benign invasive procedures or as a localized infection.[36,53] Endocarditis was documented in intravenous drug abusers and patients undergoing dialysis.[18,65] Postoperative bacteremia in eight adult patients was linked to contaminated intravenous medications infused during anesthesia.[44] Contaminated arterial catheters were implicated in an epidemic of *Chryseobacterium* bacteremia.[55] Four patients, including a 7-year-old boy, became bacteremic in an outbreak associated with contamination at the time of intracardiac surgery.[3] This organism also has been associated with bacteremia in pediatric burn patients.[51]

Chryseobacterium spp. also have been isolated from infected skin lesions manifesting as papules, sheetlike lesions, plaques, and deep panniculitis.[19] One fatal case of necrotizing fasciitis in a patient with diabetes mellitus and chronic heart failure was reported.[33] Infection may have been related to wound contamination during repair of an orthopedic injury. A woman with pemphigus vulgaris developed cellulitis and sepsis.[54] Chryseobacteria have been isolated from amputation stumps, but the bacteria may play a largely saprophytic role at these sites.[26]

DIAGNOSIS

Rapid identification of infection with these organisms is urgent, not only to ensure providing proper therapy for the patient, but also to hasten initiating appropriate infection control measures to forestall epidemic outbreaks. Identification of *E. meningosepticum* is hindered by characteristically long periods required for oxidation of carbohydrates and weak or delayed indole production. Cultures may be misidentified as species of *Achromobacter* or *Pseudomonas*.[15] Clinical isolation of an unidentified gram-negative rod that is catalase- and oxidase-positive and that shows multiple antibiotic resistance should raise suspicion of *E. meningosepticum* infection. Cultures should be kept for several days for observation for typical carbohydrate reactions, which confirm the diagnosis.[15,48] Pulse-field gel electrophoresis of DNA was used successfully to identify recurrence of intravenous catheter-associated infection in a 6-year-old boy with non-Hodgkin lymphoma.[4,50]

TREATMENT

Unfortunately, treatment of *E. meningosepticum* meningitis represents an especially difficult challenge for the physician. The organism is paradoxically likely to be sensitive to drugs commonly employed against gram-positive organisms (i.e., rifampin, vancomycin, clindamycin, and trimethoprim-sulfamethoxazole) and resistant to those used to treat gram-negative infections (i.e., aminoglycosides, cephalosporins, tetracyclines, and carbapenems). Most *Elizabethkingia* and *Chryseobacterium* spp. produce broad-spectrum metallo–β-lactamases. In *E. meningosepticum*, the enzyme is highly efficient at hydrolyzing carbapenems. Inactivation of cephalosporins displays a remarkable variability that is based on the affinity of the enzyme for the different compounds.[63] Delay in establishing a specific identification of the organism occurs commonly, so the physician knows only that the organism is gram-negative, often resulting in prolonged periods of suboptimal therapy because recommended empirical antimicrobial treatment of gram-negative neonatal meningitis usually consists of a third-generation cephalosporin or ampicillin and an aminoglycoside, drugs to which *E. meningosepticum* almost uniformly is resistant. Moreover, antimicrobial susceptibilities determined by disk diffusion must be interpreted with caution. Aber and

associates[1] found clinical isolates in which specific strains were sensitive to gentamicin and rifampin by disk diffusion but were resistant by agar gel dilution susceptibility testing. Therefore, more direct methods of measuring the minimal inhibitory concentration than disk diffusion sensitivity should be used to determine the optimal microbial agents for therapy.

Probably as a consequence of difficulties encountered in providing rapid and effective antibacterial therapy, these organisms frequently persist for prolonged periods in CSF. Average persistence of *E. meningosepticum* in CSF is 19 days,[15] in contrast to the 3.9 days described by McCracken[41] for most cases of gram-negative neonatal bacterial meningitis.

Studies of in vitro susceptibility data forced a reappraisal of the idea that vancomycin is a good first-line choice for the treatment of chryseobacterial infection. In one report, a literature review showed that only 65 percent of historic isolates were susceptible to vancomycin[4]; in another, a thorough search for a susceptible organism among 58 clinical isolates met with failure.[20] Ninety-seven percent of *E. meningosepticum* isolates were susceptible to rifampin. Clinically, drugs that have been used alone or in combination with some success have included erythromycin, vancomycin, trimethoprim-sulfamethoxazole, fluoroquinolones (especially sparfloxacin and levofloxacin), and rifampin.[59] Some of these agents have the potential disadvantage of poor penetration of CSF. Combined use of many of these drugs renders interpreting therapeutic response difficult. The 3 survivors among the 12 patients reported by George and associates[21] all received vancomycin intravenously, intrathecally, or both, as a part of their regimen. Hawley and Gump[24] reported a case of *E. meningosepticum* meningitis in a neonate who responded to systemic vancomycin after unsuccessful treatment with multiple antibiotics, including erythromycin.

Intraventricular erythromycin[17,49] or rifampin[11,34,35,49] has been used in conjunction with systemic administration of these drugs. In particular, Lee and associates[35] reported no deaths in seven infants with *E. meningosepticum* meningitis who were treated with intraventricular rifampin through an Ommaya reservoir at a dosage of 2 to 5 mg every 24 hours combined with 40 mg/kg/day administered intravenously. Intraventricular administration continued until the CSF was sterile. However, colonization of the Ommaya reservoir was a common finding, and formation of a porencephalic cyst occurred in one patient. Chandrika and Adler[11] reported sterilization of ventricles in one afflicted neonate within 48 hours after institution of therapy with intraventricular and intravenous rifampin. Erythromycin has been used intraventricularly with limited success at 5 to 10 mg/day.[17,49] Rios and associates[49] reported the successful addition of intraventricular rifampin to a failing regimen of intravenous and intraventricular erythromycin. Development of resistance during therapy has been demonstrated with erythromycin and rifampin[17,49]; persistence of organisms in the CSF despite administration of presumably adequate therapy should alert the physician to test for this possibility. Addition of trimethoprim-sulfamethoxazole may be of benefit with such an occurrence; this agent affected a bacteriologic cure in eight of nine infants with meningitis.[37] This agent usually is not recommended in the neonatal period because of possible displacement of bilirubin from albumin-binding sites. Bacterial eradication was achieved in 48 hours in two patients with meningitis who were treated with clindamycin, rifampin, and cefotaxime systemically and rifampin intraventricularly.[7]

As with other types of gram-negative meningitis, antimicrobial therapy should be continued for at least 2 weeks after sterilization of ventricular fluid has been achieved. Time to sterilization is frequently prolonged; most patients, therefore, require 4 to 6 weeks of antimicrobial therapy. Complications of hydrocephalus and the potential use of intraventricular therapy render the neurosurgeon an essential part of the management team. Historically, mortality has been in excess of 70 percent, no doubt in part because of delays in identifying the organism and the limited antibiotic spectrum available for effective therapy. More recent series of patients, although small, suggest some improvement in this statistic, but the rate of morbidity of hydrocephalus and neurologic deficits remains high.

Recovery has been the rule in immunocompetent older individuals infected with contaminated materials, often despite treatment with antibiotics to which the organism was insensitive, a finding highlighting the very low virulence of these organisms in immunocompetent adults.[39] However, significant mortality and morbidity often occur in immunocompromised individuals with bacteremia or meningitis. Use of chloramphenicol, vancomycin, levofloxacin, erythromycin, or rifampin has achieved some success in these patients, but the choice of antibiotic must be based on a detailed examination of the organism's susceptibility.[25,51]

Acknowledgments

I would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 125

Pseudomonas and Related Genera

Michael T. Brady • Mario J. Marcon

The genus *Pseudomonas* contains a large number of bacterial species, most of which are found in the soil or water as saprophytes or are plant pathogens and not associated with animal or human infections. Early attempts at better understanding the taxonomy of this diverse group of organisms led to placement of *Pseudomonas* spp. into five species clusters of genetically related organisms, also known as ribosomal RNA (rRNA) homology groups (designated groups I to V).[141] This genus since has undergone extensive revision using DNA-DNA hybridization, 16S rRNA sequencing, and related techniques, with four of the five homology groups reclassified into different genera (Table 125-1).[205] The taxon *Pseudomonas* was retained for organisms in rRNA homology group I with *P. aeruginosa* as the type species. Although they can cause infections in otherwise healthy individuals, they are more commonly opportunistic human pathogens causing disease in patients with burn wounds, cystic fibrosis, malignancy, or immunodeficiency, as well as in individuals who are malnourished, are receiving immunosuppressive therapy, or have indwelling devices. The most important species by far relating to human disease is *P. aeruginosa;* however, some other related organisms are less commonly associated with specific clinical syndromes in both children and adults. This chapter will focus on *Pseudomonas* spp. (classic rRNA group I organisms) and *Burkholderia*, *Ralstonia*, *Cupriavidus*, and *Pandoraea* spp. (classic rRNA group II and related organisms) of primary clinical significance in pediatric patients.

ETIOLOGY

Pseudomonas spp. and related genera (pseudomonads) are nonfastidious, nonfermentative, obligately aerobic (i.e., metabolize carbohydrates oxidatively and thus require molecular oxygen as the terminal hydrogen/electron acceptor), catalase positive, generally cytochrome oxidase positive and motile, non–spore-forming, gram-negative bacilli. Some species, including *P. aeruginosa*, may grow anaerobically in the presence of nitrates or other nonorganic compounds as terminal hydrogen/electron acceptors. They lack the phosphoenolpyruvate-hexose-phosphotransferase system of glycolysis and catabolize carbohydrates by the Entner-Doudoroff (aerobic, oxygen-requiring) pathway. Because pseudomonads can metabolize a wide variety of carbon sources, including simple and complex carbohydrates, alcohols, and amino acids, they can survive and multiply in almost any moist environment containing minimal amounts of organic compounds.

It is useful to discuss the *Pseudomonas* spp. (former rRNA homology group I organisms) as members of either the "fluorescent pseudomonad group" or the "nonfluorescent pseudomonad group." The fluorescent pseudomonads include *P. aeruginosa*, *P. putida*, *P. fluorescens*, and less commonly encountered species; the nonfluorescent group includes *P. stutzeri* and *P. mendocina* (stutzeri group), *P. alcaligenes* and *P. pseudoalcaligenes* (alcaligenes group), and *P. luteola* and *P. oryzihabitans* (yellow-pigmented group).

The fluorescent pseudomonads generally produce the water-soluble yellow-green fluorescent pigment pyoverdin (fluorescein), whereas many clinical isolates of *P. aeruginosa* also produce the water-soluble blue phenazine pigment pyocyanin. These pigments diffuse into and color the medium surrounding the colonies. The combination of pyoverdin and pyocyanin produced by *P. aeruginosa* combine to give the bright-green to blue-green color characteristic of this organism on certain clear laboratory media, particularly Mueller-Hinton agar. Some strains of *P. aeruginosa* may produce other pigments, such as dark red (pyorubin) or brown-black (pyomelanin) pigment.

P. aeruginosa is readily recovered from clinical specimens and usually is recognized easily on laboratory media such as sheep blood agar by its characteristic flat-spreading colonies with a metallic-sheen, an irregular edge, and production of β-hemolysis; however, atypical colony types such as smooth-round, mucoid, or small colony variants may occur, particularly in patients with cystic fibrosis. These atypical colony types are likely due to the impact of previous antibiotic therapy on synthetic biochemical pathways. It is common to recover a mixture of colony types in such patients. On selective and differential MacConkey agar, *P. aeruginosa* produces colorless colonies because lactose is not used as a sole carbohydrate source and there is no change in pH of the medium. In some situations, additional selective media containing inhibitors such as cetrimide and acetamide may be used to improve the isolation of *P. aeruginosa* from clinical specimens with mixed bacterial flora. However, in practice, such media are not commonly employed because *P. aeruginosa* is not likely to be overgrown by other organisms in patient specimens. When pigment production and typical metallic-sheen colony type are combined with a positive cytochrome oxidase test, *P. aeruginosa* can be identified with high certainty without further testing. Many laboratories rely on commercial biochemical identification systems for identifying gram-negative rods suspected of being *P. aeruginosa*, particularly those with atypical colony morphology. Most such

TABLE 125-1 Taxonomic Changes Associated with *Pseudomonas Spp* and Related Organisms Causing Disease in Humans

Rrna Homology Group	Previous Species Designation	Current Species Designation
I		*Pseudomonas aeruginosa*
		Pseudomonas fluorescens
		Pseudomonas putida
		Pseudomonas stutzeri
		Pseudomonas mendocina
		Pseudomonas pseudoalcaligenes
		Pseudomonas alcaligenes
	Chryseomonas luteola	*Pseudomonas luteola*
	Flavimonas oryzihabitans	*Pseudomonas oryzihabitans*
II	*Pseudomonas cepacia*	*Burkholderia cepacia*
	Pseudomonas gladioli	*Burkholderia gladioli*
	Pseudomonas mallei	*Burkholderia mallei*
	Pseudomonas pickettii	*Ralstonia pickettii*
	Pseudomonas pseudomallei	*Burkholderia pseudomallei*
III	*Pseudomonas acidovorans*	*Delftia acidovorans*
	Pseudomonas testosteroni	*Comamonas testosteroni*
	Pseudomonas delafieldii	*Acidovorax delafieldii*
	Hydrogenomonas facilis	*Acidovorax facilis*

systems are highly accurate (>90%) for identification of *P. aeruginosa*, but less accurate for identification of other *Pseudomonas* spp. Such systems for identification of *P. aeruginosa* isolates from patients with cystic fibrosis are less accurate, particularly for slow-growing or variant colony types. Some systems may have difficulty separating the three closely related fluorescent pseudomonads, and thus definitive identification may require additional testing. Although growth is optimal at 35° to 37°C (95° to 98.6°F), *P. aeruginosa* grows at 42°C (107.6°F) and *P. fluorescens* and *P. putida* do not. In addition, most isolates of *P. aeruginosa* reduce nitrogen to gas, whereas the other two fluorescent *Pseudomonas* spp. do not. Additional biochemical characteristics of *P. aeruginosa* include a reaction of alkaline over no change in triple sugar iron agar; production of acid oxidatively from glucose and xylose but not lactose, sucrose, or maltose; and a positive reaction for arginine dihydrolase. In practice, these latter tests are generally not used because they do not clearly differentiate among the fluorescent pseudomonads. Most strains are motile by one or more polar flagella and also display surface pili. Most isolates also carry the genes required to synthesize the extracellular mucopolysaccharide alginate, whose overproduction results in the mucoid colony type; however, such colony types are almost exclusively isolated from the respiratory tract of patients with cystic fibrosis.[222]

Among the nonfluorescent group *Pseudomonas* spp., *P. luteola* and *P. oryzihabitans* are somewhat unique because they are cytochrome oxidase negative and produce an intracellular yellow, nondiffusible pigment. Most isolates of *P. stutzeri* produce a distinctive dry, wrinkled colony on agar media, and the colonies can adhere tenaciously to the agar. In contradistinction, *P. mendocina* produces smooth colonies with a brown-yellow pigment. Isolates of *P. alcaligenes* and *P. pseudoalcaligenes* do not produce distinctive colony types and are rarely encountered in clinical specimens. As a group, these organisms are identified with variable accuracy by commercial biochemical identification systems. Depending on the clinical situation, an identification of *Pseudomonas*-like gram-negative rod or *Pseudomonas* spp., not *aeruginosa*, with a request to contact the laboratory for further identification and antimicrobial susceptibility testing may be sufficient. When definitive identification is required, nucleic acid–based methods for identification of culture isolates of *Pseudomonas* spp. have proved useful. These methods include sequencing of the genes coding for 16S rRNA or the use of specific nucleic acid probes or polymerase chain reaction (PCR) assays, such as assays targeting the exotoxin A or other *P. aeruginosa*–specific gene sequences. Peptide nucleic acid fluorescence in situ hybridization has also been shown to be sensitive and specific for identification of *P. aeruginosa*, including identification in positive blood culture bottles.

The former rRNA homology group 2 and related organisms currently comprise a diverse group of bacteria in the genera *Burkholderia*, *Ralstonia*, *Cupriavidus*, and *Pandoraea*. Like the *Pseudomonas* spp., they are found in a wide variety of environmental habitats as saprophytes, plant pathogens, and opportunistic animal and human pathogens and are nutritionally versatile. The more well-studied organisms in the group belong to the genus *Burkholderia*, which now contains about 60 species. Members of this genus can be divided into two major groups—the *B. cepacia* complex and non–*B. cepacia* complex organisms. There are currently 17 named *B. cepacia* complex organisms with all but one having been recovered from human specimens. The most important species in the complex are *B. multivorans* and *B. cenocepacia* because of their role as colonizers and opportunistic pathogens in patients with cystic fibrosis. Of the non–*B. cepacia* complex *Burkholderia* spp., those of human clinical significance include *B. gladioli* and *B. pseudomallei*. *B. gladioli* is an important

agent of respiratory tract colonization and infection in patients with cystic fibrosis.[300] *B. pseudomallei* causes melioidosis and has also been recovered from the respiratory tract of patients with cystic fibrosis. *Burkholderia mallei* is an important animal pathogen causing glanders in horses.

The genera *Ralstonia*, *Cupriavidus*, and *Pandoraea* all contain species of clinical significance, but they are recovered in culture at lower rates than *Burkholderia* spp. The genus *Ralstonia* includes at least five species, with the following species known to cause human infections: *R. pickettii*, *R. insidiosa*, and *R. mannitolitytica*.[72,73] The genus *Cupriavidus* contains at least 11 species, including *C. gilardii*, *C. respiraculi*, *C. taiwanensis*, and *C. pauculus*, the latter of which have been recovered from patients with cystic fibrosis.[333] The genus *Pandoraea* contains at least five named species (i.e., *P. apista*, *P. pulmonicola*, *P. pnomenusa*, *P. sputorum*, and *P. norimbergensis*) and several unnamed species.[74] *P. apista*, *P. pnomenusa*, and *P. sputorum* have been recovered from patients with cystic fibrosis.[108] As a group, these organisms are of low virulence and infection in healthy individuals is uncommon. They have been associated with catheter-related bloodstream infections and other health care–associated infections in immunocompromised patients and with colonization and infection in those with cystic fibrosis.

As a group, these organisms grow well but slowly on most standard laboratory media such as sheep blood, chocolate, and MacConkey agars and appear as small, smooth, raised colonies. They may appear as colorless colonies or, with prolonged incubation, pink to dark-red colonies because of the slow usage of lactose, as is usually the case with *B. cepacia* complex organisms. They are all cytochrome oxidase weak or strong positive, gram-negative, motile rods, except for *B. gladioli* and *Pandoraea* spp., which are oxidase variable. A majority of *B. cepacia* complex isolates are lysine decarboxylase positive, a helpful feature in identification of this group. Isolation of *B. cepacia* complex organisms from clinical specimens with mixed bacterial flora, particularly the respiratory tract of patients with cystic fibrosis, is enhanced by using selective and differential media with the ability to inhibit the growth of *P. aeruginosa* and other gram-negative rods. In addition, recovery may be improved if culture plates are incubated at least 3 days at 35° to 37° C (95° to 98.6° F). Several selective agar media are commercially available, including oxidative-fermentative base–polymyxin B–bacitracin–lactose (OFPBL),[346] "*P*". *cepacia* (PC), and *B. cepacia*–selective (BCSA) agars.[140,359] These media take advantage of the fact that *Burkholderia* spp. and some related organisms are generally resistant in vitro to the polymixin antibiotics, whereas *P. aeruginosa* and most commonly isolated enteric bacteria are susceptible (*Serratia* spp. are a notable exception) and therefore inhibited on such media. Several studies have shown differences in the ability of these media to recover *B. cepacia* complex organisms or to inhibit the growth of other bacterial flora, with BCSA being equivalent or superior to the other media for this purpose.[140,359] Some of these media are also useful for the recovery of *B. gladioli* from patients with cystic fibrosis.

B. pseudomallei grows on agar media commonly used for isolation of gram-negative bacteria. The colonies develop slowly (over a week) and have a characteristic "daisy-head" appearance. α-Hemolysis is noted on sheep blood agar. Ashdown selective medium, which contains crystal violet and gentamicin, can increase the recovery rate of *B. pseudomallei* from clinical specimens containing mixed bacterial flora, including throat, rectal, and sputum specimens.[15] *B. pseudomallei* produces a dry, wrinkled, violet-purple colony with a pungent, earthy odor on Ashdown medium.[205] Other selective media, including a recently described *B. pseudomallei*–selective agar (BPSA) and selective media for *B. cepacia* (BCSA, PC, and OFPBL), have been evaluated against Ashdown medium for the recovery of *B. pseudomallei*.[130,253] Ashdown medium remains the recommended medium for recovery of *B. pseudomallei* in endemic areas, but commercially available selective agars for *B. cepacia*, particularly PC agar, are acceptable media in nonendemic areas. Selective enrichment broths also have been developed for the recovery of *B. pseudomallei* from superficial sites. Such broths have been shown to improve the recovery of the organism when used in addition to direct plating onto Ashdown medium. Because of the potential of *B. pseudomallei* as an agent of bioterrorism via inhalation, isolation of the organism from patients with no travel history to endemic sites should immediately be reported to public health.

Accurate identification of the rRNA group II and related organisms may be difficult using either traditional biochemical or commercially available biochemical test systems.[121,182,273,276] Few of these species are found in the databases of such systems, and none of these systems are able to clearly differentiate among the various species in the *B. cepacia* complex. As with *P. aeruginosa*, molecular methods including amplification of the 16S rRNA gene followed by sequencing have been most widely used for this purpose; however, such methods may not always discriminate among closely related pseudomonads. Special emphasis should be given to accurate identification of such organisms when recovered from patients with cystic fibrosis, because of the clinical significance and patient management implication of a *B. cepacia* complex or related organisms in such patients. An initial, probably biochemical, identification of *B. cepacia* complex for a patient with cystic fibrosis should be confirmed with a molecular method capable of determining the exact species identification. To this end, the Cystic Fibrosis Foundation established a *B. cepacia* reference laboratory at the University of Michigan for phenotypic characterization and genotypic species identification for suspected *B. cepacia* complex and related organisms. Recently, matrix-assisted laser desorption ionization–time of flight mass (MALDI-TOF) spectrometry has received increasing attention as a method for rapid and accurate identification of bacteria, including difficult to identify organisms recovered from the respiratory tract of patients with cystic fibrosis.[215] MALDI-TOF allows for the analysis of biomolecules such as nucleic acids, proteins, and sugars, as well as other large organic molecules that may be fragile and fragment when ionized by more conventional ionization methods. The method allows for very rapid characterization of bacteria at the genus, species, and possibly the strain level.

EPIDEMIOLOGY

P. aeruginosa is a ubiquitous environmental organism found in soil, water, and on vegetation, including the surface of many raw fruits and vegetables. Its minimal nutritional requirements and ability to grow in a wide variety of physical environments enhance the organism's ability to survive in numerous ecologic niches. *P. aeruginosa* may be found as colonizing flora in a small percentage of healthy humans.[137] Sites of colonization include moist body sites and mucosal surfaces such as throat, nasal mucosa, axillae, and perineum. Carriage rates in the gastrointestinal tract have been reported as high as 24 percent based on selective culture of stool. The gastrointestinal tract may be the site of transient colonization after ingestion of food or liquids containing *P. aeruginosa*. Despite the ability to colonize skin and mucosal surfaces, it rarely results in persistent colonization. The respiratory tract is a common site of colonization of patients who have been hospitalized for extended periods, have foreign bodies in place (i.e., endotracheal tubes or tracheostomies), have poor mucociliary clearance, or have received broad-spectrum antibiotics or chemotherapy.

P. aeruginosa is best classified as an opportunistic pathogen whose pathogenic potential is manifest in situations in which the host's immune defenses are diminished or lacking. Such situations include children with poor mucociliary clearance (cystic fibrosis), neutropenia (secondary to cancer chemotherapy), or damaged skin barrier (burn wound).The organism generally does not invade intact skin or mucous membranes.

P. aeruginosa frequently enters the hospital environment on the clothes and shoes of patients, visitors, or hospital personnel and also from the same individuals with skin, gastrointestinal tract, or respiratory tract colonization. It may also enter the hospital on plants or flowers. As a result, the organism may be found growing in any moist hospital environment, including hospital kitchens and laundries, mops, shower heads, whirlpools, antiseptic solutions, eye drops, distilled water sources, irrigation fluid, dialysis fluid, and equipment used for dialysis and respiratory care or inhalation therapy. It tolerates elevated temperatures and can grow in distilled water sources containing only inorganic compounds. *P. aeruginosa* commonly is found on the surface of many types of plants and flowers, raw fruits, and vegetables. Consumption of these foods by profoundly immunosuppressed children can result in colonization of the gastrointestinal tract and potentially can lead to invasive disease. In hospitalized patients, the likelihood of colonization increases with duration of hospitalization. Transmission of *P. aeruginosa* from patient to patient or from hospital personnel to patient often is assumed but rarely documented.[12,13,92,350] Although clear evidence exists of patient-to-patient transmission of "epidemic strains" of *P. aeruginosa* among the cystic fibrosis population, the relative importance of this mode of acquisition as opposed to acquisition from environmental sources is unclear.[3,132,204] Environmental sources of *P. aeruginosa* outside the hospital that may result in colonization with subsequent infection include swimming pools, water slides, hot tubs, contact lens solutions, cosmetics, illicit injectable drugs, and the inner soles of sneakers.

Various typing systems have been used to characterize strains of *P. aeruginosa* for epidemiologic purposes; these can be classified as either phenotypic or genotypic typing methods. Historically, the phenotypic method of serologic typing based on the O-polysaccharide component of lipopolysaccharide was used most often, but some strains of *P. aeruginosa* lack the O-polysaccharide. Other phenotypic typing methods include phage and pyocin typing. These methods have limited ability to differentiate strains, particularly from chronic infections because of the variability of gene expression in this organism. Phenotypic methods have been replaced by genotypic methods, including restriction fragment length polymorphism (RFLP) analysis, pulsed-field gel electrophoresis (PFGE), random amplified polymorphic DNA (RAPD) analysis, multilocus sequence typing (MLST), and others.[77,315] Each of these methods has certain advantages and disadvantages in terms of cost, complexity, and discriminatory power. They have proved helpful in demonstrating, for example, that patients with cystic fibrosis were usually infected with unique strains of *P. aeruginosa* that they harbored for extended periods rather than being replaced by other strains.

The environmental distribution of the other *Pseudomonas* spp. is similar to that of *P. aeruginosa*, and hospitalized as well as nonhospitalized individuals can become transiently colonized. Infection may infrequently occur, particularly in individuals who are immunocompromised. *P. fluorescens* can be isolated from the skin.[298] *P. fluorescens* has been responsible for transfusion-associated bacteremia in blood recipients, likely as a result of contamination during blood collection.[298] In addition, contamination of blood with *P. fluorescens* during the blood culture collection process has been responsible for outbreaks of pseudobacteremia.[177,306] *Pseudomonas pseudoalcaligenes* has one of the more unusual environmental habitats—industrial metalworking fluid consisting of a mixture of water and petroleum products. Although metalworkers with long-term exposure to aerosols containing high concentrations ($>10^5$ organisms/mL) of *P. pseudoalcaligenes* develop high antibody titers to the organism, they do not have clinical evidence of acute or chronic respiratory or systemic disease.[216] Limited data exist on typing systems for *Pseudomonas* spp. other than *P. aeruginosa*.

B. cepacia complex and related organisms are ubiquitous in nature and can be found in water, soil, decaying organic matter, and as plant pathogens.[153,195,334] Unlike *P. aeruginosa*, *B. cepacia* complex organisms are infrequently encountered in the hospital environment or nonhospital sites such as swimming pools, sinks and showers. As a group, these organisms are intrinsically resistant to disinfectants and a wide range of antimicrobial agents, including the aminoglycosides and carboxypenicillins (e.g., ticarcillin and carbenicillin). Moreover, resistance can be acquired to quinolones, extended-spectrum penicillin/β-lactamase inhibitor compounds, third- and fourth-generation cephalosporins and carbapenem antibiotics. *B. cepacia* can survive for extended periods in moist environments, even in the presence of disinfectants, including povidone-iodine.[8] These organisms have

been identified as agents of sporadic nosocomial outbreaks of infection in medical intensive care units. When such outbreaks occur, they have been traced to contaminated instruments and solutions, such as in automated peritoneal dialysis machines, blood gas analyzers, mouthwashes, ultrasound gels, medications, and skin antiseptics, including povidone-iodine and chlorhexidine.[27,28,139,311] In patients with cystic fibrosis, colonization of the respiratory tract, sometimes associated with lower respiratory tract and disseminated infection, is of major clinical significance because of the association of this organism group with increased morbidity and mortality.[132,154,205] Although acquisition of *B. cepacia* complex organisms from the environment is the more common mode of transmission, as evidenced by the fact that the majority of infected patients harbor genetically distinct strains, epidemiologic investigations have clearly demonstrated "epidemic strains" and interpatient transmission in the cystic fibrosis population.[20,32] Most data suggest that once colonized with a specific strain, replacement of that strain with another strain occurs infrequently.[29] *B. cepacia* complex organisms also have become more important as a cause of infection and complications in patients with chronic granulomatous disease[316] and sickle-cell hemoglobinopathies.[30]

B. gladioli, like *B. cepacia* complex organisms, is a plant pathogen found in water and soil. It is associated with infections in immunocompromised patients, including patients with chronic granulomatous disease and in patients with cystic fibrosis. In fact, it is recovered more frequently from patients with cystic fibrosis than most *B. cepacia* complex species other than *B. cenocepacia* and *B. multivorans*. *B. pseudomallei*, the causative agent of melioidosis, and the closely related species *B. thailandensis*, are found in soil and surface water in the tropical and subtropical areas of Southeast Asia and northern Australia, including rice paddy surface waters in rice-growing areas of Thailand, Cambodia, Vietnam, and Laos.[63,81,312] *Ralstonia*, *Cupriavidus*, and *Pandoraea* spp. are also found in soil and water sources, but their epidemiology has not been well studied. Unlike some *B. cepacia* complex species, person-to-person transmission of other *Burkholderia* spp. or *Ralstonia*, *Cupriavidus*, and *Pandoraea* spp. has been rarely reported.

Genotypic typing systems have been applied to epidemiologic investigations of *B. cepacia* complex organisms, other *Burkholderia* spp., and species of other genera in this group.

PATHOGENESIS

Among the *Pseudomonas* spp., the pathogenesis of infections with *P. aeruginosa* has been well studied. Pathogenesis is multifactorial,[24,208] and the outcome of *P. aeruginosa*–host encounters depends on a variety of organism-specific and host factors. To establish lung infection, for example, *P. aeruginosa* must contend with the mucociliary clearance mechanism and innate immunity, including antibacterial peptides such as lactoferrin, and the action of phagocytic cells.[285] The large genome of the organism provides it with the metabolic flexibility to adapt to various host environments. A large number of varied and redundant virulence factors include cell-associated (bound to the bacterial cell surface) and extracellular proteins and other macromolecules, which are either injected directly into the host cell cytoplasm or secreted into the general extracellular environment.[335] These factors, along with intrinsic and acquired resistance to antimicrobial agents, allow the organism to colonize, resist host defense mechanisms, produce local tissue damage, and in some situations invade and result in disseminated infection despite the host immune response.[351]

Expression of virulence factors is under tight regulatory control and depends on the body site and type of infection. Different factors may be expressed in acute versus chronic infections. Two major types of regulatory systems promote organism survival and proliferation. The first system type involves one- or two-component transcriptional regulatory secretion of exoproteins. One-step systems promote direct delivery of preformed exoproteins, whereas two-step systems synthesize exoproteins as precursor molecules requiring cleavage before exporting outside the cell.[131] In either case, exoproteins are delivered across the inner and outer cell membranes and peptidoglycan cell wall layer to the periplasmic space. The second regulatory system type involves quorum-sensing regulatory systems that help coordinate gene expression throughout the bacterial population to aid the organism in adapting to environmental conditions. Quorum-sensing systems involve cell-to-cell signaling by production of small diffusible molecules known as autoinducers. Quorum sensing plays an important role in promoting the formation of biofilms on mucosal surfaces and internalized medical devices. Such biofilms are important for survival of the organism and contribute to persistent and chronic infections. Interestingly, macrolide antibiotics, which do not inhibit growth of *P. aeruginosa* in vitro, may inhibit quorum sensing and biofilm formation.[328,335]

P. aeruginosa displays virtually all known classes of microbial virulence factors. Cell-associated virulence factors include flagella, pili, and endotoxin (lipopolysaccharide). Flagella and pili play an important role in establishment of initial infection because of their functions of providing motility and binding to specific epithelial cell surface receptors. *P. aeruginosa* has one or more polar flagella that allow for motility and appear to be important in initial stages of lung colonization. The flagella themselves do not appear to enhance binding to epithelial cells, but they do bind to respiratory mucin produced in response to infection and may contribute to other cell-binding mechanisms. Decreased clearance of mucin in the lung of some individuals may contribute to establishment of infection. Flagellar proteins contribute to excess activation of proinflammatory cytokines. Once infection is established in the lung, flagella are generally no longer produced, and they are usually not found in organisms associated with biofilms. Strains of *P. aeruginosa* that lack flagella are less capable of dissemination from wounds and less likely to cause bacteremia and pneumonia in animal models.[14,94,106] Pili, like flagella, are also found at the poles of the *P. aeruginosa* rod. They promote

adherence to mucosal epithelial cells by binding to specific cell-surface glycolipids.[338] They also mediate twitching motility, which appears to be important in biofilm formation, as demonstrated by in vitro models.

Other cell surface adhesions likely exist, including outer membrane proteins and oligosaccharides that work in complement with flagella and pili to promote initial colonization of cell surfaces by *P. aeruginosa*. The cystic fibrosis transmembrane conductance regulator (CFTR) protein also may play an important role as an epithelial cell receptor for *P. aeruginosa*. The CFTR protein appears to be involved with bacterial internalization and clearance from the lung.[297] Diminished internalization of bacteria in murine and primate models of cystic fibrosis might provide some basis for hypersusceptibility of cystic fibrosis patients to infections with *P. aeruginosa*.[297]

P. aeruginosa endotoxin is not as potent as are the endotoxins produced by other gram-negative organisms, including *Escherichia coli* (2 to 3 mg is needed to kill a 20-g mouse). The oligosaccharide side chain of *P. aeruginosa* endotoxin prevents lysis by complement and the lipid moiety triggers cytokine pathways that lead to the sepsis syndrome and shock. The virulence of *P. aeruginosa* in a mouse burn model was found to be related directly to lipopolysaccharide integrity.[79] Deficiency of the O side chain of lipopolysaccharide reduced virulence markedly.[260]

Extracellular virulence factors of *P. aeruginosa* include numerous exotoxins with proteolytic or lipolytic activity. These include the elastolytic proteases LasA protease and elastase (LasB), collagenase, gelatinase, caseinase, alkaline protease, fibrinolysin, phospholipase C (a thermolabile hemolysin), lecithinase, exotoxin A, and a group of exoenzymes including ExoS, ExoT, ExoU, and ExoY. The proteolytic enzymes may be responsible for localized necrosis of the skin or lung tissue and for corneal ulceration. The various proteases also can degrade plasma proteins, including complement and coagulation factors.[358] Solubilization and destruction of lecithin (surfactant) may play a role in the atelectasis seen in pulmonary infections caused by *P. aeruginosa*. Fibronectin protects epithelial cells from bacterial attachment, but its ability to do so is reduced in patients with cystic fibrosis because of the high level of proteases in respiratory secretions and also after cellular injury from trauma, intubation, or postviral infection.

Exotoxin A is an adenosine-5′-diphosphate ribosyltransferase enzyme that inhibits eukaryotic cell protein synthesis by a mechanism similar to the action of diphtheria toxin. Specific exotoxin A–deficient mutants of *P. aeruginosa* have reduced virulence in mouse and rat models of corneal and lung infection.[244,356] Exotoxin A also diminishes the activity of host phagocytes. Passive or active immunization against exotoxin A significantly protects against experimental infection with exotoxin A–producing strains of *P. aeruginosa*. Phospholipase C degrades phospholipids, which are plentiful in eukaryotic but not prokaryotic cell membranes. The hemolysis produced by *P. aeruginosa* may be caused by heat-labile phospholipase C and by a heat-stable moiety.

The exoenzymes S, T, U, and Y have multiple enzymatic and chemical functions. Their secretion is regulated by a type III secretion system commonly found in other bacterial pathogens. This system is associated with acute infections, requires pilin-mediated contact with target epithelial cells, and allows the organism to directly inject these products into the host cell cytoplasm rather than simply into the general environment. ExoS and ExoT are bifunctional proteins that display GTPase activation and ADP-ribosyltransferase activity. They confer antiphagocytic activity by depolarizing actin filaments and thus disrupting normal cytoskeletal organization. ExoS also inhibits interleukin production by alveolar macrophages and induces tumor necrosis factor-α production. Production of ExoS is associated with invasive disease in burn patients. *P. aeruginosa* growing on the burn wound but not on intact skin produces ExoS,[238] and ExoS can be found in the blood of patients who develop *P. aeruginosa* sepsis before the bacteria can be detected. *P. aeruginosa* strains that do not produce ExoS are less able to cause invasive disease.[291] ExoU is a potent cytotoxin possessing phospholipase A2 activity and causing rapid damage to cell membranes and cell death. ExoY has adenylate cyclase activity, but its specific role in virulence is unclear.

The importance of type III secretion proteins in the pathogenicity of *P. aeruginosa* has been demonstrated in animal model systems. Neutralization of these proteins has been shown to prevent septic shock and improve survival in a mouse model system. Similarly, antibodies against PcrV, a protein involved in translocation of the exoenzymes, resulted in complete survival of the animals. Rabbit model studies of *P. aeruginosa*–induced septic shock after lung injury also showed the protective effect of antibodies to PcrV.

Among the vast array of proteases produced by *P. aeruginosa*, the elastolytic enzymes, LasA and LasB, cause direct damage to lung tissue (elastin accounts for 30% of the protein of lung tissue) and can also interfere with immune clearance of *P. aeruginosa* from the lungs. Berger and associates[25] noted that elastase treatment of isolated polymorphonuclear leukocytes severely impaired their ability to kill opsonized *P. aeruginosa*. They demonstrated proteolytic degradation of C3b receptors and suggested that it may contribute to the inability of patients with cystic fibrosis to eradicate *P. aeruginosa* from their lungs. Because several cell types, including macrophages, monocytes, B-lymphocytes, and some T-lymphocytes, carry the same C3b receptor, the proteolytic activity may cleave this molecule from all these cells, thereby decreasing the phagocytic activity of monocytes and macrophages in these patients. Berger and colleagues[25] also demonstrated that optimal interaction between the complement-derived opsonic ligands C3b and iC3b and their respective receptors does not occur in the milieu of the lungs of patients with cystic fibrosis who are infected with *P. aeruginosa*. They suggested that both *P. aeruginosa* and host proteases may contribute to the initiation of a cycle of events in which neutrophils entering the infected lung actually impair phagocytosis rather than eradicate the source of infection. Breakdown of elastin in the walls of blood vessels might be responsible for the intrapulmonary hemorrhage noted in individuals with cystic fibrosis.

P. aeruginosa also produces siderophores, including pyoverdin and pyochelin; these are iron-scavenging compounds that allow the organism to replicate in an iron-deficient environment. Iron in host tissue is tightly bound to transferrin or lactoferrin in the lungs. Siderophores bind iron efficiently and then are taken up by the bacterium through cell-specific receptors. Siderophores also play a role in control of expression of other virulence factors.

Mucociliary clearance is impeded in patients with cystic fibrosis, and, as a consequence, they fail to cleanse the bronchopulmonary epithelium of inhaled particles, including bacteria.[185,227] *P. aeruginosa* adherence to the airways of children with cystic fibrosis may be enhanced by the acidic environment that results from the hyperacidification of the trans-Golgi network from the dysfunctional CFTR protein in lung epithelial cells.[264] The specific colonizing strain or strains of *P. aeruginosa* may reflect exposure to other colonized individuals in health care facilities, cystic fibrosis camps, or at home, as well as by selective pressure by the use of mist tents, inhalation therapy, and continuous broad-spectrum antibiotic therapy.[184,373]

The evolution of colonization from the nonmucoid to the mucoid phenotype of *P. aeruginosa* can be correlated with the patient's age, clinical score, extent of pulmonary function abnormalities, severity of changes on chest radiographs, and serum immunoglobulin levels.[67,68] The specific lung environment of a patient with cystic fibrosis is believed to trigger a switch to a cluster of genes that code for abundant production of alginate, thereby giving rise to the mucoid phenotype.[67,318] Strains of *P. aeruginosa* expressing the mucoid phenotype are rarely recovered from patients without cystic fibrosis (0.5% to 1.7%). Chronic infection of the lungs in patients with cystic fibrosis selects for additional genetic adaptations by *P. aeruginosa*, including the loss of genes coding for virulence factors (primarily proteins) required for initiation of acute infections.[308] The loss of such virulence factors may contribute to a decrease in the immunogenicity of the organism, a diminished effective immune response, and the inability of the host to eradicate *P. aeruginosa* from the airways.

Persistence of *P. aeruginosa* within the respiratory tract is aided by growth of the organism in microcolonies embedded in a biofilm of alginate.[145,148,254] This biofilm allows nutrients to pass while protecting the organism from host defense mechanisms, antibodies, and antibiotics.[186] In addition, investigators have noted that rabbit alveolar macrophages fail to phagocytize and kill the organism in the presence of serum from patients with cystic fibrosis. This phenomenon suggests that these patients have a specific, local defect in pulmonary resistance to *P. aeruginosa*.

The mucoid strains of *P. aeruginosa* isolated from the respiratory secretions of patients with cystic fibrosis produce large quantities of the mucopolysaccharide alginate, which is composed of acetylated D-mannuronic acid and L-glucuronic acid.[67,317] This polysaccharide polymer not only gives *P. aeruginosa* a mucoid appearance on agar medium but also has antiphagocytic activity. Alginate elicits a significant inflammatory immune response in the lungs of patients with cystic fibrosis and may contribute to the lung damage that occurs in chronic *P. aeruginosa* lung infection.[219] Because of its viscous nature, alginate contributes to the thick bronchial secretions in the lungs of children with cystic fibrosis; these secretions obstruct small airways and impair mucociliary clearance and movement of phagocytic cells. Production of alginate by *P. aeruginosa* is regulated and inducible. Mucoid isolates of *P. aeruginosa* lose the mucoid trait when serially cultured on laboratory media. Nonmucoid isolates convert to the mucoid phenotype when inoculated into the lung in a rat model.[291] Alginate also inhibits the action of antibiotics.[146]

The predilection for *P. aeruginosa* to colonize and infect the respiratory tract of patients with cystic fibrosis may partially be the result of decreased oxygen tension within the hyperviscous mucous layer.[357] Epithelial cells in individuals with cystic fibrosis have increased oxygen usage, which is responsible for the decreased oxygen tension.[357] This local hypoxia results in a change in the phenotype of *P. aeruginosa* resulting in alginate production, decreased motility (loss of flagella), and biofilm production.[357] Once these phenotypic changes occur, eradication of *P. aeruginosa* from the lungs of individuals with cystic fibrosis is nearly impossible.

The pathogenicity of *P. aeruginosa* also depends on its ability to resist or overwhelm host cell defense mechanisms. Fick and Reynolds[110,111] noted that in patients with cystic fibrosis, the opsonic function of IgG was reduced as a result of a molecular change in the Fc portion of the immunoglobulin (Ig)G molecule. This deficit was magnified in the lungs of patients with cystic fibrosis infected with *P. aeruginosa* because bacterial proteases can fragment IgG and further impair its opsonic activity. The persistence of *P. aeruginosa* in the lungs of patients with cystic fibrosis also may be related to the presence of one or more factors in their respiratory secretions that interfere with the bactericidal activity of fresh normal human serum against *P. aeruginosa*. These "blocking factors" have been shown to be IgG antibody that inhibit the normal bactericidal activity of human sera IgM antibody.[256,296]

Concentrations of IgG subclass immunoglobulins have been studied in patients with cystic fibrosis and compared with values obtained in age-matched healthy children and adults. Pressler and associates[265] noted that in 52 percent of patients with cystic fibrosis, at least one of the four IgG subclasses had an elevated serum concentration in contrast to controls. A significant correlation of elevated serum concentrations of IgG2 (and to a lesser extent IgG3) with decreased forced expiratory volume at 1 second was noted. Moss[228] found that patients with cystic fibrosis who are infected with *P. aeruginosa* have markedly elevated serum concentrations of IgG antibodies to the opsonic immunodeterminant, type-specific lipopolysaccharide. This elevation was distributed among all four IgG subclasses with a significant shift toward IgG3. Sera from patients with cystic fibrosis who were colonized with *P. aeruginosa* had diminished opsonic capacity, but complement-dependent human neutrophil phagocytosis was not impaired. Serum concentrations of IgG4 but not IgG1, IgG2, or IgG3 are correlated

inversely with opsonic capacity. On the basis of these data, Moss[228] suggested that high levels of IgG4 antibody to opsonic immunodeterminants may inhibit normal pulmonary clearance of *P. aeruginosa* by pulmonary macrophages in vivo. In addition to alterations in humoral immune responses to *P. aeruginosa*, it appears that dysfunctional CFTR also alters the bacterial activity of macrophages against *P. aeruginosa*.[87]

Infection of the lower respiratory tract in patients with cystic fibrosis results in massive infiltration of lung tissue with neutrophils.[75,93] The neutrophils release elastolytic enzymes that overwhelm the ability of protease-inhibiting compounds of the lung to protect against tissue damage. This results in destruction of lung tissue and accumulation of large amounts of extracellular nucleic acid and cell cytosol matrix, which contributes to airway viscosity.[85]

Virulence factors of other *Pseudomonas* spp., *B. cepacia* complex, and related organisms have been less well studied but include their ability to adhere to indwelling devices and elaboration of exoenzymes such as elastase and gelatinase.[231] *B. cepacia* complex has numerous important virulence factors, some of which play a specific role in the clinical syndromes seen in patients with cystic fibrosis. *P. aeruginosa* enhances subsequent adhesion to epithelial surfaces by *B. cepacia*,[288] suggesting a synergistic relationship between the two bacterial pathogens, particularly in patients with cystic fibrosis.[314] Additionally, *B. cepacia* complex strains from cystic fibrosis patients with the most severe progression bind most avidly to mucin.[289] *B. cepacia* also resists nonoxidative neutrophil killing.[316] These organisms are intrinsically resistant to many antimicrobial agents. The following host-specific factors increase the risk for colonization with these organisms, as well as progression from colonization to infection: (1) prolonged hospitalization, especially in intensive care settings[216]; (2) administration of broad-spectrum antibiotics[318]; (3) malignancy, particularly if associated with immunosuppressive therapy and neutropenia[179,318]; and (4) breaks in mucocutaneous defense barriers, chiefly by instrumentation or the use of invasive devices.[179]

As with most pathogens, the pathogenicity of *B. pseudomallei* is related to both virulence factors of the organism and the host's immune response to infection and in many ways resembles the types of infections and clinical outcomes associated with *P. aeruginosa* and to some extent *B. cepacia* complex organisms. As a saprophyte associated with soil and surface waters, the organism can survive harsh environmental conditions, including extremes of temperature, pH, and levels of moisture.[63] Moreover, the organism also resists the action of many antiseptics, disinfectants, and antibiotics. Altered phenotypes of the organism may be found in culture of clinical material, including small-colony variants with increased antibiotic resistance, as are seen in chronic infection with *P. aeruginosa*.

B. pseudomallei produces a variety of exoenzymes secreted into the environment, including proteases, lipases, lecithinase, phospholipase C, and hemolysins.[63] The organism also has type III secretion systems, as are found in many pathogens, including *P. aeruginosa*. These systems allow for delivery of effector molecules directly into host cells and may allow the organism to survive in phagosomes and promote tissue invasion. Interestingly, the closely related *B. thailandensis* does not have type III secretion systems and is significantly less virulent. Cell-associated virulence factors include extracellular polysaccharide capsule, lipopolysaccharide, and outer membrane proteins and proteins associated with flagella and pili. As a group, these factors contribute to attachment to epithelial cells and protection against host immune responses, and they may contribute to biofilm formation. Notwithstanding a wide array of virulence factors, *B. pseudomallei* generally has a low potential for causing disease in humans, as evidenced by the high rates of seropositivity in asymptomatic individuals in endemic areas and the increased likelihood of causing disease in individuals with predisposing factors.[63]

CLINICAL MANIFESTATIONS

Previously Healthy Children

P. aeruginosa can produce disease in previously healthy, immunocompetent children.* When such infections occur, the source of the organism is water, soil, or vegetative or related contaminated material, and the organism has gained entry though the skin or mucous membrane by a minor or penetrating wound. After entry, the organism may produce a localized infection with cellulitis that may progress to abscess formation and may be associated with a green or blue-green exudate. The skin lesions, whether caused by direct inoculation or secondary to septicemia, begin as pink macules that progress to small cutaneous hemorrhagic nodules and eventually to areas of necrosis, with eschar formation surrounded by an intense red areola (ecthyma gangrenosum, Fig. 125-1).[230,271] In addition to skin infections, previously healthy children may experience localized and systemic infections, including corneal infection, dacryocystitis,[374] otitis externa, mastoiditis, mastitis, urinary tract infection, septicemia, endocarditis, bone and joint infections, peritonitis, meningitis, pneumonia, and necrotizing fasciitis.[232]

Outbreaks of dermatitis (folliculitis; "hot-tub syndrome"), plantar nodules ("hot-foot syndrome"), otitis externa, mastitis, and urinary tract infections caused by *P. aeruginosa* have been reported in normal, healthy children after the use of community swimming pools, water slides, recreational whirlpools, or family-owned hot tubs.† Pruritic or painful skin lesions (5 to 30 mm) develop several hours to 5 days or longer (mean, 48 hours) after contact with these water sources. Subcutaneous involvement, including mastitis, has been reported.[122] Skin lesions may be erythematous, macular, or pustular. In some cases, very tender nodules have been observed.[113] Illness may vary from a few scattered lesions in some patients to extensive truncal involvement in others. The rash is most severe in areas occluded by snug-fitting bathing suits. In some children, malaise, fever, otitis

externa, vomiting, sore throat, conjunctivitis, rhinitis, pyuria, abdominal cramps, and swollen breasts may be associated with the dermal lesions. Rarely, this recreational water-associated *P. aeruginosa* infection can present with an acute onset of exquisitely painful plantar nodules.[113,369] Skin biopsy of the tender nodules reveals perivascular and perieccrine neutrophilic infiltrate and microabscesses.[113] Laboratory evaluations reveal leukocytosis with increased proportions of neutrophils and elevations of the sedimentation rate and C-reactive protein.[113]

Multiple serotypes of *P. aeruginosa* have been associated with these outbreaks. The use of whirlpool baths usually involves soaking in water for variable periods. Superhydration of skin and exposure to *P. aeruginosa* result in primary cutaneous infection.[146] Whirlpool water is heated to temperatures above 37.8° C (100° F) and frequently is not filtered, thereby allowing for the persistence of desquamated skin. Both of these factors are conducive to growth of *P. aeruginosa*.

Otitis externa caused by *P. aeruginosa* has been reported in healthy competitive swimmers who swim repetitively in a pool contaminated with *P. aeruginosa*.[270] The organism also has been associated with a more malignant form of otitis externa manifested as high fever, necrosis of portions of the external ear, facial nerve paralysis, mastoiditis, and osteomyelitis of the temporal bone and basilar skull.[151,233] Rarely, *P. aeruginosa* meningitis results from progression of this infection.[262] Malignant otitis externa usually is associated with predisposing factors such as malnutrition, leukopenia (a disorder of leukocyte function), malignancy, or diabetes mellitus. Successful management of malignant otitis externa requires aggressive surgical débridement in addition to appropriate systemic antibiotic therapy.

P. aeruginosa is a common agent of chronic suppurative otitis media (with or without cholesteatoma), and acute and chronic mastoiditis.[56,175,240] Chronic suppurative otitis media is a complication of inadequately treated acute otitis media and is manifested as a perforated tympanic membrane with persistent otorrhea. Chronic suppurative otitis media also occurs in children with surgically induced perforations of the tympanic membrane by tympanostomy tubes and incompletely or inadequately treated otitis media. The microbial agents of acute otitis media in children with tympanostomy tubes differ from those in children with intact tympanic membranes. *P. aeruginosa* has been recovered from 12 percent of children with acute otitis media and tympanostomy tubes.[278] When tympanostomy tubes become colonized with *P. aeruginosa*, eradication may be complicated by the production of a biofilm.[39] The presence of a biofilm will reduce effectiveness of conventional systemic and topical antimicrobial therapy. Outpatient therapy with oral antibiotics frequently is unsuccessful because of a lack of oral antimicrobial agents with antipseudomonal activity. Topical ciprofloxacin with or without dexamethasone has been shown to be effective and superior to oral amoxicillin–clavulanic acid in the treatment of acute otitis media in children with otorrhea through tympanostomy tubes.[91] Intravenous antibiotics targeting the bacterial agents isolated from middle ear aspirates may be needed to cure chronic suppurative otitis media. This therapy may preclude the necessity of performing tympanomastoid surgery, which becomes essential in those with extensive granulation tissue and osteitis in the mastoid.[51]

P. aeruginosa wound infections of the ear have occurred after commercial ear piercing, resulting in perichondritis.[171] Upper ear cartilage is more commonly involved than lobe piercing. In one report reuse of a "single-use" disinfectant bottle contaminated at a sink harboring *P. aeruginosa* was implicated.[171]

P. aeruginosa infections of the eye usually occur after minor trauma or surgery, with deposition of a large inoculum topically, or by hematogenous spread. The use of contaminated contact lens solution or the use of tap water during contact lens care, as well as endotracheal suctioning without covering the eyes of sedated or comatose patients have been implicated in dacryocystitis, keratitis, and blepharoconjunctivitis.[46,143,147,149] Use of topical steroids, exposure to contaminated ocular medications, and prior ocular irradiation can predispose to keratitis. Infection of the cornea can result in ulceration, which may progress to more invasive disease, including endophthalmitis. Most cases of endophthalmitis in children result from penetrating ocular injuries or as a postoperative complication of surgery. Loss of vision may result, even if appropriate antimicrobial therapy is administered promptly.

Urinary tract infection (UTI) caused by *P. aeruginosa* occurs rarely in healthy children. More typically, pseudomonal UTI occurs in children who are catheterized or have had instrumentation or surgery on their urinary tract or who were immunocompromised.[246] UTI resulting from *P. aeruginosa* primarily occurs as a result of ascending infection; however, the urinary tract may become infected secondary to bacteremia. The symptoms of pseudomonal UTI are not usually different from those of UTI caused by other bacteria. Because of differing antibiotic susceptibilities of *P. aeruginosa* and the underlying medical condition of the child with a pseudomonal UTI, antimicrobial therapy and clinical response to therapy may differ.

P. aeruginosa is the most common cause of osteomyelitis after puncture wounds of the foot and is responsible for more than 90 percent of cases.[43,102,225] The calcaneus or metatarsal bones commonly are affected.[78] Symptoms may be present for 2 to 40 days (mean, 9 days) before diagnosis is made and hospitalization is needed.[78] Pain and swelling are the most common symptoms; fever and wound drainage rarely are noted. Leukocytosis (white blood cell count >10,000/mm^3) and an elevated erythrocyte sedimentation rate are present in most patients. Radiographs of the affected foot usually show evidence of osteomyelitis at some time during the period of evaluation and treatment. Bone scan results almost universally are abnormal and frequently yield evidence of osteomyelitis before positive findings on radiographs. The inner pad of sneakers has been implicated as a possible source of *P. aeruginosa* in these patients[115]; however, *P. aeruginosa* osteomyelitis of the foot bones has developed when the puncture occurred through other types of footwear or while the child was barefoot.[114]

Other *P. aeruginosa* infections of bones and joints are uncommon findings in children. When they do occur,

they are the result of hematogenous spread of *P. aeruginosa* in patients who are intravenous drug abusers or who have urinary tract or pelvic infections. Although any bone or joint may be associated with a bacteremic episode, *P. aeruginosa* has a unique predilection for the vertebrae, sternoarticular joints, pelvis, and symphysis pubis. The clinical course of *P. aeruginosa* osteomyelitis or septic arthritis is more indolent than that occurring after infection with *Staphylococcus aureus*. Contiguous spread can occur after penetrating trauma, surgery, or overlying soft tissue infections, especially decubitus ulcers.

P. aeruginosa may produce serious infections in healthy neonates. Septicemia may be noted in the earliest hours of life and is associated with high morbidity and mortality. In utero acquisition of the organism resulting in intraamniotic infection (amnionitis), neonatal sepsis, and death has been described.[241,282,331,370] The clinical course is similar to that of any other form of gram-negative septicemia, with hypotension, respiratory distress, and skin lesions being the predominant manifestations. Mortality rates may be as high as 80 percent.[160] Late-onset neonatal *P. aeruginosa* infection usually occurs as a nosocomial infection (i.e., bacteremia, urinary tract infection, and pneumonia) associated with a foreign body (e.g., indwelling urinary or vascular catheter or endotracheal tube) in hospitalized infants. An outbreak in a neonatal intensive care unit of *P. aeruginosa* pneumonia and bloodstream infection was determined to be associated with intermittent otitis externa in a health care worker.[371] Maternal colonization after the use of a hot tub for relaxation during labor was responsible for *P. aeruginosa* meningitis and bacteremia in an 11-day-old infant.[340]

Other pseudomonads (except *B. pseudomallei*) rarely cause disease in healthy persons. Reports in normal, healthy children, particularly when the children have been hospitalized in an intensive care unit,[35] include pneumonia, keratitis,[203] and abscesses caused by *B. cepacia* complex organisms; abscesses caused by *P. fluorescens;* and otitis media, pneumonia, and osteomyelitis[53,280] caused by *P. stutzeri.* A penetrating lawn dart resulted in a mixed flora brain abscess with *Pseudomonas paucimobilis.*[329] Peritonitis and septicemia caused by *B. cepacia* complex organisms have been associated with contamination of equipment used for peritoneal dialysis.[27]

Melioidosis is a rare disease of Southeast Asia and northern Australia that increased in frequency in the United States when Americans returned from Vietnam, Honduras,[58] or El Salvador[56] and, rarely, after immigration by Southeast Asians.[81,250] The causative agent is *B. pseudomallei*, an environmental saprophyte of soil and water in the tropics, particularly in rice paddies.[190] Infection occurs after contact of abrasions or wounds with contaminated soil or water, inhalation of contaminated dust, or ingestion of contaminated water. Patients with poorly controlled diabetes, renal disease, or immunocompromised conditions caused by collagen vascular disease, hematologic malignancies, or immunosuppressive therapy appear to have an increased risk for development of disease after infection with *B. pseudomallei*.[201]

Transmission most commonly occurs after percutaneous inoculation. Inhalation and ingestion are less common modes of transmission. Hematogenous spread occurs after local infection. Transmission from animals to humans has not been reported. The rat flea *(Xenopsylla cheopis)* and the *Aedes aegypti* mosquito have been reported to infect animals with *B. pseudomallei*, but it is unclear whether this route of infection is associated with human cases.[248] Human-to-human transmission has occurred during sexual or prolonged close contact.[120] Two cases of mother-to-child transmission of *B. pseudomallei* occurred through breast milk.[267] One mother had obvious mastitis.[267] An outbreak of melioidosis in Australia was traced to a potable water source from a water treatment plant that had irregularities in purification.[153]

Most infections with *B. pseudomallei* remain subclinical.[201] Melioidosis can have a broad spectrum of clinical signs, and symptoms may be latent for months or years before the disease becomes clinically apparent. The initial clinical finding may be a single primary skin lesion (i.e., vesicle, pustule, bulla, or urticaria) in a patient with no underlying disease. Septicemia occasionally occurs, and multiple abscesses may be noted in every organ of the body. The mortality rate associated with fulminant sepsis approaches 90 percent.[188] Meningitis; encephalitis; arthritis; nodular pulmonary densities; abscesses of liver,[11] lung, spleen, kidney, and bones; and endophthalmitis have been observed in both normal and compromised hosts after or concomitant with an episode of septicemia. The acute septicemic illness is indistinguishable from other types of septicemia caused by gram-negative organisms.

B. pseudomallei can cause myocarditis, pericarditis, endocarditis, intestinal abscess, cholecystitis, acute gastroenteritis, UTI, septic arthritis, paraspinal abscess, osteomyelitis, hilar lymphadenopathy, and cervical lymphadenopathy. Parotitis was documented in 38 percent of 126 children with melioidosis in Thailand.[82] None of the 126 children with melioidosis had any apparent predisposition to infection.

Subacute melioidosis generally is characterized by an illness lasting weeks to months. Pulmonary infection in this form of disease is a common occurrence and may mimic tuberculosis. The disease can vary from mild bronchitis to severe, fulminant pneumonitis, and lung consolidation and cavitations occur frequently.[188,221]

Neonatal melioidosis has been reported in Thailand.[213] Infants with neonatal septicemia, meningitis, or both caused by *B. pseudomallei* have been described. The mode of transmission of this organism to these newborn infants is not always clear. A clear case of mother-to-child transmission of *B. pseudomallei* has been reported.[2] The mother had acute melioidosis treated with ofloxacin at 32 weeks' gestation. Consolidation of the right lung of the infant occurred, and an abscess eventually developed. Postpartum cultures of the mother's cervix yielded *B. pseudomallei*.

Chronic melioidosis occurs more frequently in whites than in Asians.[217] Chronic melioidosis may involve every organ in the body, including the brain.[188] Melioidosis may become dormant, with exacerbations occurring years after primary infection when host defenses are impaired as a result of steroid use, burns, diabetes mellitus, or other processes. The longest latent period (24 years) was reported by Kingston.[181]

Melioidosis should be considered in any person who has been to Southeast Asia or northern Australia at any time and has fever of unknown origin, overwhelming sepsis, single or multiple abscesses, or any tuberculosis-like illness. The diagnosis is established by culture of blood, skin lesions, or purulent material from an abscess cavity or from other sites of infection.[62]

Burn Wounds

The surface of burn wounds and skin grafts are frequently colonized by pseudomonads and other gram-negative organisms.[105] Colonization does not always progress to infection, but it is a necessary prerequisite to development of invasive disease. Septicemia with *P. aeruginosa* is a major problem in burn patients, with the mortality rates of burn wound sepsis approaching 78 percent.[220] Systemic involvement may be related to multiplication of organisms in devitalized surface areas with subsequent invasion of healthy tissue and dissemination, or it can be associated with prolonged use of intravenous or urinary catheterization required for the care of these patients. The use of antibiotics for prophylaxis may diminish the susceptible microbiologic flora but select for resistant strains of *P. aeruginosa*. In addition, the hydrotherapy that is commonly provided to burn patients promotes colonization of the burned area and other body sites.[330]

In burn patients, abnormalities in neutrophil function that precede the onset of septicemia have been described.[57] Killing of *P. aeruginosa* by neutrophils is impaired. Burn injury is also associated with abnormal responses to microbial antigens, delayed rejection of homografts, abnormal vascular responses, impaired delayed hypersensitivity responses, diminished uptake of foreign substances particles by the reticuloendothelial system, and altered antimicrobial pharmacokinetics. Contamination of wounds with high concentrations of bacteria in excess of 10^5 colony-forming units per gram of tissue impedes contraction and healing of the wound.[252] In addition, *P. aeruginosa* produces numerous substances that can further inhibit the natural healing process of burns and wounds. Exogenous plasminogen activators and proteases break down proteins such as fibrin and halt the contraction process.[258] *P. aeruginosa* ExoA, a protein synthesis inhibitor, also contributes to retardation of wound healing.[138] Secondary bacterial infection results in nearly 25 percent of skin graft loss after full- or split-thickness skin grafts.[332] *P. aeruginosa* was responsible for nearly 60 percent of the infections that resulted in skin graft loss. Skin graft loss was more common when the skin grafts were performed on the lower extremities and when grafts were applied at multiple sites.[332] Skin graft infections with *P. aeruginosa* were more severe and resulted in a fourfold increase in reoperation rates.[332]

Cystic Fibrosis

Cystic fibrosis is one of the most common lethal inherited diseases of children.[105,229] It is a generalized disorder of salt and water transport that affects the exocrine glands and is caused by mutations in the CFTR gene.[186,279] The course and prognosis of disease are determined largely by chronic infections of the airways with opportunistic bacteria and death usually resulting from destructive pneumonitis and chronic obstructive pulmonary disease. *P. aeruginosa* is the most common respiratory bacterial pathogen recovered from patients with cystic fibrosis. A 2008 U.S. surveillance study reported that slightly more than 50 percent of patients with cystic fibrosis had *P. aeruginosa* recovered from sputum cultures.[22,204] The prevalence varied by age, ranging from 25 percent for children younger than 5 years of age to 80 percent for adults in the 25- to 34-year-old group.[204,272] Initial recovery of *P. aeruginosa* from the respiratory tract of a child with cystic fibrosis may represent colonization and not infection. Colonization rates are higher in such children, who require pancreatic enzyme supplementation. Colonization is followed by infection, which is intermittent and usually associated with multiple strains of *P. aeruginosa*. At some point, colonization and subsequent infections by a single strain that expresses the mucoid phenotype is the norm, and eradication of the organism with antimicrobial therapy is impossible.[21,112,128,304]

Infection in patients with cystic fibrosis is limited almost entirely to the respiratory tract, and pulmonary exacerbations with endobronchial disease are a common finding.[84,144] Infection of the pulmonary parenchyma rarely occurs. Rather, the epithelium of the airways and the submucosa are edematous and contain infiltrates of chronic inflammatory cells. Documentation of a pulmonary exacerbation in cystic fibrosis relies heavily on clinical impression (e.g., increase in the frequency of productive cough; increase in volume or a change in characteristics of the sputum; increase in the respiratory rate or dyspnea; and decrease in appetite, activity, or exercise tolerance). Fever and leukocytosis are present in a minority of patients and are associated with poorer pulmonary function test results and a worse prognostic score.[307] Concentrations of *P. aeruginosa*, host cell DNA (derived from polymorphonuclear leukocytes and to a lesser extent from respiratory epithelial cells), and total protein in sputum are increased during pulmonary exacerbations and decrease significantly after antimicrobial therapy.[307] Bronchitis, bronchiolitis, and bronchiectasis can occur. Eventually, local necrotizing pneumonitis may be noted, in contrast to the overwhelming generalized necrotizing pneumonitis seen in immunosuppressed patients. Septicemia is a rare occurrence, but *P. aeruginosa* bacteremia may develop in patients with indwelling venous catheters. Colonization of lungs with *P. aeruginosa* after lung transplantation in patients with cystic fibrosis is common and occurs in the early posttransplantation period.[187]

B. cepacia complex organisms have emerged as agents of asymptomatic colonization, pneumonia, and septicemia in patients with cystic fibrosis. Although *B. cenocepacia* previously was the most common *B. cepacia* complex species isolated from patients with cystic fibrosis in the United States, *B. multivorans* now is the most common species, accounting for more than one third of clinical isolates and responsible for over half of new *Burkholderia* spp. infections.[204] Some members of the complex are more commonly associated with acute clinical deterioration

(cepacia syndrome), in particular *B. cenocepacia*[52,162,211,214]; however, other species, such as *B. multivorans*, have also been associated with the cepacia syndrome[34] and *B. dolosa*, an uncommonly encountered species, is associated with a rapid deterioration in lung function and decreased survival.[52,167]

The prevalence of infection with *B. cepacia* complex organisms in the United States generally ranges from 3 to 4 percent, with rates as high as 8 percent having been reported.[204] The higher frequency of colonization of the respiratory tract with *B. cepacia* complex in patients with cystic fibrosis has been associated with increased morbidity and mortality rates in some cystic fibrosis centers since the 1980s. The risk for colonization with *B. cepacia* complex increases with the severity of underlying disease and increasing age.[326] The source or mode of transmission of the organism has not been defined adequately[206,207,327]; but person-to-person transmission has been documented.[163] Nosocomial transmission (i.e., patient-to-patient and contaminated inhalation therapy equipment-to-patient) within cystic fibrosis centers and social contact, particularly at summer camps, is one mode of acquisition of new infection. Nonetheless, the majority of new infections with *B. cepacia* complex organisms are likely to be the result of acquisition of unrelated strains from the natural environment.

Once colonization with *B. cepacia* complex has been identified in patients with cystic fibrosis, three distinct clinical patterns have been noted: (1) chronic asymptomatic carriage, usually in association with *P. aeruginosa;* (2) progressive deterioration over many months with recurrent acute pulmonary exacerbations accompanied by fever, progressive weight loss, leukocytosis, and an elevated erythrocyte sedimentation rate; and (3) rapid, usually fatal deterioration in pulmonary function associated with necrotizing pneumonia and sometimes bacteremia ("cepacia syndrome").[155,211] The last complication can occur even in patients whose respiratory status was affected only mildly before acquiring *B. cepacia* complex infection.

Malignancy, Immunosuppression, and Other Predisposing Conditions

Children with leukemia, particularly those receiving immunosuppressive therapy and those who are neutropenic, are extremely susceptible to septicemia caused by *P. aeruginosa* and other pseudomonads.[105] Some pseudomonads, including *P. putida*, have been reported as causes of septicemia in children with malignancy.[6] Infection generally results from invasion of the bloodstream by a colonizing *Pseudomonas* spp. (e.g., from the gastrointestinal tract). Anorexia, malaise, nausea, vomiting, diarrhea, and fever may be noted. Generalized vasculitis develops, and hemorrhagic necrotic lesions can be found in all organs, including the skin, where they appear as purple nodules or ecchymotic areas that become gangrenous.[269] Other invasive *P. aeruginosa* infections noted in children receiving immunosuppressive chemotherapy include hemorrhagic gangrenous perirectal cellulitis or abscess, typhlitis, preseptal cellulitis, and necrotizing fasciitis.[209,223,337]

Children undergoing treatment for malignancies are particularly vulnerable to bacterial infection. Chemotherapy and radiation therapy can disrupt mucocutaneous barriers and result in moderate to severe immunosuppression. Fergie and associates[107] described 98 children and adolescents with cancer in whom *P. aeruginosa* bacteremia developed; the rate of bacteremia was highest in patients with leukemia. Most cases occurred when patients had absolute neutrophil counts of less than 100/mm^3. Mortality associated with *P. aeruginosa* bacteremia was higher in patients with solid tumors, an absolute neutrophil count of less than 100/mm,[5] perineal skin lesions, and bacteremia during remission or induction therapy rather than during a relapse.

The single most important factor that predisposes children with cancer to infection is granulocytopenia. The bactericidal capacity of children with leukemia and other neoplasms also may be impaired. Heat-stable opsonins specific for *P. aeruginosa* likewise may fall precipitously in children with acute leukemia who are receiving intensive combination chemotherapy. Fatal infections with *P. aeruginosa* may be related in part to deficiency of this specific opsonin.

Immunosuppressive agents may be used in the management of malignancies, transplantation, or collagen vascular disease. The location of the infectious process and the type of causative organisms depend somewhat on the underlying disease. Infection by *P. aeruginosa*, particularly pneumonia and septicemia, occurs more commonly in children receiving immunosuppressive therapy than in the normal, healthy population.

P. aeruginosa is a major cause of health care–associated infections in children and is particularly associated with the use of implantable medical devices. Infections of intrathecal baclofen pumps used to manage spasticity have been associated with wound infections and meningitis.[361] Delayed infections in cochlear implant recipients with *P. aeruginosa* have been reported.[125] *P. aeruginosa* is a leading cause of nosocomial respiratory tract infection in children undergoing mechanical ventilation or receiving inhalation therapy.[186] Asymptomatic colonization of the upper and lower airways occurs commonly and should be distinguished from respiratory tract disease, tracheitis, and pneumonia. A predominance of gram-negative bacilli with an abundance of polymorphonuclear leukocytes on Gram stain of lower respiratory tract secretions, in conjunction with a positive culture for *P. aeruginosa*, strongly supports the role of *P. aeruginosa* as the causative agent for the lower respiratory tract infection. Absence of *P. aeruginosa* from lower respiratory tract secretions markedly reduces the likelihood that *P. aeruginosa* is in the lower respiratory tract. In these cases of device-associated infection, removal of the device is important for successful management of the infection.

Septicemia resulting from *P. aeruginosa* occurs with increased frequency in children with indwelling vascular or urinary catheters.[322] Urinary tract infections also have been associated with cystoscopic examination. In addition, septicemia may occur in children with congenital or acquired neutropenia or in persons with a functional deficit in polymorphonuclear leukocyte function. *P. aeruginosa* is a common cause of abscesses and meningitis in

children with dermoid sinus tracts or dermoids extending down to or communicating with the meninges or neural tissue and in children with meningomyelocele.

Endocarditis caused by *P. aeruginosa* must be considered in children and adolescents with prosthetic valves or other intracardiac synthetic material. The organism also may produce acute or subacute endocarditis in children with congenital cardiac lesions before or after cardiac surgery and on both native and prosthetic heart valves. Tricuspid valve involvement occurs most commonly, but involvement of multiple valves is possible with *P. aeruginosa;* the manifestations are typical of subacute endocarditis. If the left side of the heart is involved (i.e., aortic or mitral valves), the patient has acute and more fulminant disease. Fever and heart murmur are almost universal findings. Fortunately, endocarditis is an uncommon occurrence in the pediatric population because its usual setting is in adolescents and adults who inject illicit drugs. Other *Pseudomonas* spp. have been rarely associated with post–cardiac surgery infections.[115]

P. aeruginosa needs to be considered in children and adolescents at risk for acquiring human immunodeficiency virus (HIV) infection, primarily after severe immunodeficiency has occurred.[116,277,313] Risks for acquiring *P. aeruginosa* infection in HIV-infected individuals include hospital exposure, declining $CD4^+$ cell count, and the use of dapsone or trimethoprim-sulfamethoxazole (TMP-SMX); azithromycin use was protective.[264,313] Bacteremia may occur with or without the presence of an indwelling vascular catheter. Fever, hypotension, skin lesions (i.e., papules or ecthyma gangrenosum), and pneumonia are common manifestations.[116] Mortality rates can be high, particularly when empiric antimicrobial therapy is inadequate for the treatment of severe, invasive *P. aeruginosa* infection. *P. aeruginosa* supraglottitis has been reported in a 6-month-old child with severe combined immunodeficiency syndrome.[194]

B. cepacia complex organisms can cause opportunistic infections in patients other than those with cystic fibrosis, primarily in hospitalized or immunocompromised patients. These include nosocomial pneumonia in patients on ventilation, bacteremia, wound infections, urinary tract infections, meningitis, endocarditis, and skin lesions. *B. cepacia* complex organisms are also an important cause of infections in patients with chronic granulomatous disease (CGD) because of the organism's ability to resist killing by defective neutrophils using nonoxidative pathways. Bacteria that cause most infections in CGD are catalase-positive organisms. The CGD-affected neutrophil can kill numerous microorganisms despite its defects because most microorganisms endogenously produce hydrogen peroxide, which the CGD-affected neutrophil can modify and use against the organism in the phagosome. Whereas both *P. aeruginosa* and *B. cepacia* are catalase-positive organisms, the former is a rare pathogen in CGD because CGD neutrophils can kill *P. aeruginosa* organisms by means of nonoxidative mechanisms. Fortunately, all of these infections are uncommon findings in children.

P. putida has been primarily associated with health care–associated infection, particularly in the neonatal intensive care unit. Most cases present as bacteremia or as cutaneous infections.* Cutaneous manifestations reported in neonates with *P. putida* have an appearance similar to that of staphylococcal scalded skin syndrome.[193] Mortality rates after infection with *P. putida* are high because of vulnerability of the patients and inappropriate empirical antibiotic therapy.[193] *Pseudomonas putida* is typically susceptible to antipseudomonal β-lactam antibiotics and carbapenems but not reliably susceptible to aminoglycosides.[193]

P. fluorescens causes disease primarily in immunocompromised patients who have been inadvertently exposed to contaminated infusion fluids, disinfectants, and drinking water.[101,126,150,178,353] Most infections result in fever; systemic reactions of sepsis and mortality have been reported but are not typical. *P. fluorescens* is usually susceptible to carbapenems, aminoglycosides, and tetracycline[150]; however, *P. fluorescens* is less likely to be susceptible to third-generation cephalosporins and trimethoprim.[150] Mupirocin, a topical antibiotic, is produced through fermentation of *P. fluorescens*.

P. stutzeri has been responsible for a diverse group of clinical conditions, with wound infections being the most common presentation.[237] Bacteremia is the second most common presentation and usually results from exposure to contaminated infusion fluids.[239] Pneumonia, UTI, and skin and eye infections have also been reported. Most patients with presumed *P. stutzeri* infections are hospitalized and have predisposing conditions that make them vulnerable to opportunistic organism.[237] *P. stutzeri* are typically susceptible to antipseudomonal penicillins and cephalosporins, aminoglycosides, and TMP-SMX.

P. mendocina is a recently described opportunistic pathogen.[239] Bacteremia, osteomyelitis, subphrenic abscess, meningitis, and wound infections have been reported.[66,159,239] *P. mendocina* is typically susceptible to carbapenems, third-generation cephalosporins, aminoglycosides, and ciprofloxacin[239]; however, resistance to some or all of these antibiotics has been reported.[239]

Ralstonia spp., especially *R. pickettii*, have caused infections in immunocompromised patients and in those with cystic fibrosis.† *Ralstonia* spp. infections such as catheter-associated bloodstream infections or health care–associated pneumonia have been reported in association with contamination of infusion fluids or respiratory equipment.‡ *Ralstonia* spp. have been reported to be susceptible to antipseudomonal β-lactams, ciprofloxacin, and TMP-SMX, and some isolates susceptible to aminoglycosides.[85,320,372] However, some strains may be resistant to antibiotics typically considered susceptible.[85,372] Susceptibility testing on clinical organisms is important to guide appropriate therapy. Catheter-associated bloodstream infections may require catheter removal to affect a cure.[183]

Most infections with *Cupriavidus* and *Pandoraea* have occurred in immunocompromised individuals or in those with cystic fibrosis. *Cupriavidus* spp. has resulted in bacteremia, skin and wound infections, and respiratory

tract colonization.[168,170,196,321] *Pandoraea* spp. have been associated with severe lung disease and systemic infection in persons with cystic fibrosis.[161,164,324] Transmission among patients with cystic fibrosis has been documented.[161,164,324]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of *P. aeruginosa* and other pseudomonad infections depends on recovery of the organism from a normally sterile body site such as blood, cerebrospinal fluid (CSF), joint fluid, peritoneal or peritoneal dialysis fluid, or deep tissue obtained in a manner that avoids contamination by cutaneous flora (see previous discussion on etiology). Diagnosis of UTI often requires suprapubic aspiration or urethral catheterization for young children. Purulent material associated with subcutaneous abscesses or areas of cellulitis should be obtained by needle aspiration. A diagnosis of *P. aeruginosa* pneumonia can be made by needle aspiration of the lung and, less convincingly, by recovery of the organism from sputum obtained by postural drainage of a child with cystic fibrosis. Recovery of the organism from the surface of the skin or the throat, a tracheal aspirate, or bronchial secretions may reflect colonization and is not necessarily diagnostic of infection. The validity of a positive culture is enhanced when it is associated with a typical clinical syndrome (e.g., *P. aeruginosa* recovered from a skin lesion typical of "whirlpool" folliculitis). Isolation of *P. aeruginosa* from the respiratory tract, particularly when obtained from an endotracheal tube in an intubated patient, is not an unusual occurrence. Differentiating colonization from infection is clinically important. Gram stain of respiratory secretions obtained by endotracheal suction typically reveals abundant gram-negative rods and polymorphonuclear leukocytes in the setting of a true lower respiratory tract infection caused by *P. aeruginosa* (tracheitis or pneumonitis). An absence of gram-negative rods or the presence of squamous epithelial cells rather than polymorphonuclear leukocytes indicates that either the patient does not have a lower respiratory tract infection or, if an infection is present, the etiologic agent is not likely to be *P. aeruginosa*.

The presence of bluish, nodular skin lesions and the ulcers with ecchymotic and gangrenous centers and bright areolae (ecthyma gangrenosum) have been considered virtually pathognomonic of *P. aeruginosa* infection. Rarely, skin lesions that are clinically indistinguishable from those caused by *P. aeruginosa* develop after septicemia secondary to *Aeromonas hydrophila*.[302] Cutaneous or disseminated infections with *Aspergillus* and *Fusarium* spp. in immunocompromised patients also can cause the necrotic skin lesions of ecthyma gangrenosum.

Isolation of *Pseudomonas*, *Burkholderia*, and other related species other than *P. aeruginosa* from clinical specimens occurs far less frequently. Recovery of these organisms from sites that normally are sterile, such as blood or blood product containers, always should be considered clinically significant unless proved otherwise.

Aside from culture diagnosis, serologic tests have been investigated for the diagnosis of *P. aeruginosa* infection, but these are generally not recommended. Although specific IgG and IgA serum antibodies to *P. aeruginosa* surface antigens, including outer membrane proteins, alginate, and lipopolysaccharide, may be detected by enzyme-linked immunosorbent assay (ELISA), immunoblotting,[45,303] and other methods, serodiagnosis is not clinically useful for diagnosis of acute *P. aeruginosa* infection. Antibody titer increases are associated with chronic, active disease in patients with cystic fibrosis, and titers returned to baseline when *P. aeruginosa* infection was controlled by effective antimicrobial therapy. Nonetheless, little consensus exists regarding the clinical value of their measurement in cystic fibrosis, except perhaps in patients in whom the initial appearance of antibodies predates culture positivity[347] and a positive serology indicates the onset of *P. aeruginosa* infection. Moreover, no standardized assay protocols exist and it is difficult to determine the relative positive and negative predictive values of such assays.

In contrast to serologic diagnosis of *P. aeruginosa* infection, serologic tests may be useful in establishing the diagnosis of melioidosis, particularly in latent or asymptomatic forms of this disease.[4,235] Hemagglutination, indirect hemagglutination, complement fixation, ELISA, and immunoblot assays have been used.* Diagnostic sensitivity of these serologic tests is highly variable. High rates of seropositivity in populations in endemic areas also limit specificity.[16,65,362] Hemagglutination A antibodies generally are present within 7 to 14 days after onset of the illness, whereas the complement fixation test yields positive results in 4 to 6 weeks. Maximal titers for both tests are reached in 4 to 6 months, and detectable antibodies may persist for months to years after initial infection. The indirect hemagglutination test, although not currently available commercially, is used by the Centers for Disease Control and Prevention (CDC) for the diagnosis of melioidosis.[632] The test uses sheep red blood cells sensitized with *B. pseudomallei* antigens in a microwell format.

The interpretation of all serologic tests for melioidosis is complicated by the fact that there are no generally accepted cutoff values defining acute infection or exposure. Serologic tests are of limited value in patients living in endemic areas because of the rate of seropositivity of such individuals. Serology is valuable in individuals who do not reside in but have recently traveled to endemic areas. Paired sera should be tested whenever possible, but a single high-titer serum sample collected from a patient with a relevant travel history and a clinically consistent presentation may be helpful. Because some individuals with culture-proved melioidosis do not have detectable antibodies, a negative serologic test does not rule out infection.[136]

Several direct antigen detection assays have been developed for the rapid detection of *B. pseudomallei* in clinical specimens. These include latex agglutination, ELISA, or direct fluorescent antibody detection[10,310,363] on purulent discharges, blood, or body fluid specimens.

*References 17, 64, 135, 192, 202, 354.

As with many other antigen detection assays, the sensitivity of these assays precludes their use as stand-alone tests. Reagents for antigen detection tests for *B. pseudomallei* are not available commercially. Gram stain and immunofluorescent stains are simpler and cheaper than antigen detection assays.

PCR and other molecular methods have been used to detect *P. aeruginosa* directly in clinical specimens, particularly in respiratory specimens from patients with cystic fibrosis.[89,210] Some studies suggest that PCR may be useful in detecting *P. aeruginosa* in sputa of cystic fibrosis patients several months before culture diagnosis and at a time before establishment of chronic infection. This would allow for earlier aggressive antibiotic therapy to eradicate the organisms at a time when eradication may be possible. Other studies have suggested that PCR performed directly on clinical specimens does not significantly increase detection of *P. aeruginosa* in contrast to culture. In addition, it is difficult to interpret the clinical significance of a positive PCR and a negative culture on the same sample; a false-positive PCR result cannot easily be ruled out. Subsequent culture-confirmed colonization occurring weeks to months later may or may not be due to colonization by the same strain initially "detected" by PCR.

PCR-based and other molecular assays also have been applied to direct detection of pseudomonads other than *P. aeruginosa*, including *B. cepacia* complex organisms and *B. pseudomallei*. The same difficulty in interpreting PCR results for *P. aeruginosa* in patients with cystic fibrosis applies to *B. cepacia* complex organisms. There have been more studies on the diagnostic accuracy of nucleic acid amplification methods for direct detection of *B. pseudomallei* in clinical specimens.[60,119,166,325] Sensitivity of PCR is highest when performed on specimen types such as body fluids and purulent discharges than on blood, reflective of the bacterial load in the specimen. PCR, when available, may be used as an adjunct to but not a replacement for culture. At this point, molecular assays for the pseudomonads must be considered only investigational.

TREATMENT

Selection of Antimicrobial Therapy

Suspected or proved systemic infections with *P. aeruginosa* should be treated promptly with empirical therapy to include an aminoglycoside (i.e., gentamicin, tobramycin, or amikacin) combined with a β-lactam antibiotic (i.e., antipseudomonal penicillin, third- or fourth-generation cephalosporin, or carbapenem) pending in vitro susceptibility test results.[9,33,176] The combination of an aminoglycoside and a β-lactam antibiotic may be synergistic against the organism. However, because of increasing antibiotic resistance, dual therapy is typically used in empirical therapy to improve the opportunity that the antibiotic regimen contains at least one antibiotic to which the *P. aeruginosa* is susceptible. Rifampin is synergistic in vitro with the antipseudomonal penicillin and aminoglycoside combination therapy and may be added if the clinical response is not adequate. Antibiotic therapy should be adjusted once the results of in vitro susceptibility tests are known.[127]

Community-acquired *P. aeruginosa* infections are typically susceptible to antipseudomonal penicillins, including penicillin and β-lactamase inhibitor combinations; ceftazidime; cefepime; carbapenem antibiotics, including meropenem, imipenem, and doripenem, but not ertapenem; aminoglycosides; and quinolone antibiotics, including ciprofloxacin and levofloxacin.[172] Susceptibility is less predictable for aztreonam, a monobactam. Strains of *P. aeruginosa* causing health care–associated infections are more likely to be antibiotic-resistant than strains causing community-acquired infections. Response to treatment may be impaired when systemic infection occurs in an immunocompromised host, thus requiring a prolonged course of therapy.

Prior use of a specific antibiotic for treatment of infections caused by *P. aeruginosa* may be associated with emergence of resistance.[100,249] Specifically, monotherapy with antipseudomonal β-lactam antibiotics (i.e., antipseudomonal penicillins, cephalosporins, and carbapenems), as well as with the fluoroquinolones, has resulted in selection of resistant mutants during therapy,[23,299] including selection of multidrug-resistant mutants.[86,249] Combination therapy to include an aminoglycoside, although unlikely to have a significant effect on initial clinical response, has been suggested as a means for reducing the development of resistance while on treatment, and some studies support the use of combination therapy for this reason.[95,286,342] Some studies found that the use of antipseudomonal β-lactam antibiotics alone, which are rapidly bactericidal to *P. aeruginosa*,[118] is as effective as use of an antipseudomonal β-lactam antibiotic and aminoglycoside combination regimen for preventing the emergence of antibiotic resistance.[251] Combination therapy with two β-lactam antibiotics is inappropriate for serious *Pseudomonas* infections because the induction of β-lactamase by one of the agents may result in resistance to both antibiotics.

Table 125-2 provides dosages of some of the more commonly prescribed antipseudomonal antibiotics.[41] These dosages are only guidelines, because the doses of some of these antibiotics may vary with different clinical situations and patient populations. Once-daily administration of an aminoglycoside may decrease nephrotoxicity and improve clinical efficacy. Aminoglycoside doses must be decreased, preferably by increasing the dosing interval, in patients with diminished creatinine clearance (e.g., renal impairment, neonates). Significantly higher doses (e.g., gentamicin or tobramycin 7 to 12 mg/kg/day) may be required for patients with increased total plasma clearance, such as those with cystic fibrosis and burns. Therefore, aminoglycoside therapy must be individualized and doses guided by pharmacokinetic information. "Extended-infusion" (4-hour infusion every 8 hours) of β-lactam antibiotics (e.g., piperacillin-tazobactam) has been used to enhance the duration of drug concentration that remains above the minimum inhibitory concentration (MIC) of *P. aeruginosa*.[212]

Endocarditis caused by *P. aeruginosa* requires aggressive medical and surgical therapy. Despite combination therapy with maximal β-lactam and aminoglycoside

TABLE 125-2 **Dosages of Commonly Prescribed Antipseudomonal Antibiotics**

Generic Name	Dosage (mg/kg/day)	Route	Dosing Interval	Pediatric Precautions
Antipseudomonal Penicillins				
Ticarcillin-clavulanate	200-300 (ticarcillin) (max 12-18 g/day)	IV	q4-6h	
Piperacillin-tazobactam	240-300 (piperacillin) (max 12-16 g/day)	IV	q6h	PDNE
Cephalosporins				
Ceftazidime	200-300	IV, IM	q8h	
Cefepime	100-150 (max 2-6 g/day)	IV, IM	q8-12h	
Aminoglycosides				
Gentamicin sulfate	3-7.5 (7-10 for patients with cystic fibrosis)	IV, IM	q8h; or q24h	
Tobramycin sulfate	3-7.5 (7-10 for patients with cystic fibrosis)	IV, IM	q8h; or q24h	
Amikacin sulfate	15-22.5	IV, IM	q8h; or q24h	
Quinolones				
Ciprofloxacin	40 for PO 20-30 for IV (max 3-6 g/day)	PO, IV	q12h	>18 yr
Levofloxacin	Respiratory tract infections	PO, IV	q12h	
Moxifloxacin	<5 yr: 20 ≥5 yr:10	PO, IV	q24h	
Monobactams				
Aztreonam	90-120 (max 3-6 g/day)	IV, IM	q6-8h	
Aztreonam (75-mg solution)	≥7 yr: 75 mg/dose via altered nebulizer	Inhaled	q8h	
Carbapenems				
Imipenem-cilastatin sodium	60-100	IV IM (≥12y)	q6h	SNE
Meropenem	60 (max 3 g/day) Meningitis: 120 (max 6 g/day)	IV	q8h	
Other				
Colistimethate	2.5-5 (based on ideal body weight) (max 5-7 based on ideal body weight)	IV, IM	q8h	

IM, Intramuscular; *IV,* intravenous; *PDNE,* pediatric dose not yet established; *SNE,* safety in children not yet established.

antibiotics, valve replacement (i.e., native and prosthetic) frequently is required for cure. When gentamicin or tobramycin is administered in three divided doses per day, peak concentrations should be maintained between 12 to 15 μg/mL. Quinolones should be reserved for patients who are intolerant of aminoglycosides or whose bacteria are resistant to aminoglycosides or for long-term suppression of *P. aeruginosa* prosthetic valve endocarditis.

Meningitis or brain abscess resulting from *P. aeruginosa* should be treated with ceftazidime 200 to 300 mg/kg/day in four divided doses every 6 hours and an aminoglycoside given intravenously. The initial empirical choice of the aminoglycoside should be guided by local susceptibility patterns. Concomitant intraventricular or intrathecal treatment with gentamicin may be required if initial intravenous therapy fails to sterilize the CSF. Gentamicin can be placed into the ventricular or lumbar CSF in a total dose of 1 to 5 mg once each day (the dose is independent of body weight). Meropenem has good penetration into CSF and can be used when the *P. aeruginosa* is ceftazidime-resistant. Meropenem is the preferred carbapenem because the high doses of imipenem required to treat central nervous system (CNS) infections may be associated with CNS toxicity. Fluoroquinolones such as parenteral ciprofloxacin or pefloxacin and aztreonam are possible alternatives in the treatment of *P. aeruginosa* CNS infections if more conventional therapy has failed; however, experience with these agents for CNS infections is limited.[181,200,238] Ocular infection with *P. aeruginosa* can be serious and sight-threatening. *P. aeruginosa* corneal ulcerations or keratitis may be seen in contact lens wearers or in intubated, sedated patients in intensive care units. Topical therapy with ticarcillin, piperacillin, tobramycin, gentamicin, amikacin, ciprofloxacin, or ofloxacin may be used and is effective. Clinical efficacy is improved by frequently clearing inflammatory debris and topical application of antibiotics. Initially, antibiotic solutions should be administered

every 15 to 30 minutes. The frequency can be decreased gradually to four to six times per day when clinical improvement is apparent.

P. aeruginosa endophthalmitis frequently occurs after invasive eye surgery or penetrating injuries. Systemic, topical, and intraocular (i.e., anterior chamber and vitreous cavity) routes all are required. Even with aggressive medical intervention, return of retinal function is not a common occurrence. The prognosis is worse when initiation of therapy is delayed. Ceftazidime, imipenem, and ciprofloxacin have greater intraocular penetration than do the aminoglycosides.[368] Initial therapy for *P. aeruginosa* endophthalmitis should include ceftazidime and an aminoglycoside (e.g., tobramycin or amikacin).[42] Cefepime, meropenem, or imipenem would be potential alternatives to ceftazidime if susceptibility testing suggest that they would provide an advantage over ceftazidime. However, no clinical data support the use of these alternative antibiotics.[42]

Chronic suppurative otitis media may be due to a variety of organisms, including *P. aeruginosa*. Obtaining cultures from the middle ear is extremely valuable in determining optimal antimicrobial therapy. In most cases, therapy with a fluoroquinolone available as a topical otic compound (i.e., ciprofloxacin, ofloxacin, or besifloxacin) with or without steroids is effective.[42] Because middle ear drainage typically represents perforation of the tympanic membrane, aminoglycoside including neomycin-containing topical therapy should not be used because of potential aminoglycoside ototoxicity. Malignant otitis externa and chronic mastoiditis caused by *P. aeruginosa* require systemic antipseudomonal antibiotic therapy. Surgical débridement also may be required for effective management.

P. aeruginosa folliculitis and plantar nodules generally are self-limited and do not usually require specific antimicrobial therapy. More severe cases can be treated by the topical application of any of the following: 2.5 percent acetic acid compresses (vinegar is 5% acetic acid), gentamicin ointment, topical 0.1 percent polymyxin B, or silver sulfadiazine (Silvadene).

Skin abscesses or abscesses in other locations caused by *P. aeruginosa* should be incised and drained.[269] Failure to do so may result in a poor response despite prolonged systemic antibiotic treatment. *P. aeruginosa* may be part of multiorganism infections causing necrotizing fasciitis. Empirical therapy for necrotizing fasciitis should include antibiotics with activity against *P. aeruginosa*. Skin lesions consistent with ecthyma gangrenosum always require empirical therapy to contain antipseudomonal antibiotics.

Osteomyelitis of foot bones from *P. aeruginosa* (e.g., osteochondritis after a puncture wound) requires surgical débridement in every case. Appropriate antibiotics for 7 to 10 days after surgery appears to be adequate if surgery has removed the infected tissue effectively. Oral ciprofloxacin is an appropriate alternative antibiotic to complete antimicrobial therapy after surgery and evidence of *P. aeruginosa* as a causative agent. The adequacy of surgical débridement of the foot bones and clinical improvement can be monitored by serial sedimentation rates.[78] *P. aeruginosa* infection of foreign bodies (e.g., vascular, peritoneal, and CNS catheters) may require removal of the foreign material to cure the infection, particularly if a tunnel or exit-site infection exists.

Management of UTIs caused by *P. aeruginosa* will depend on the clinical situation of the infected child, that is, presence or absence of septicemia, instrumentation, and the anatomic location of the infection. Symptomatic pseudomonal UTIs should be treated. In patients who are clinically stable and not immunocompromised, a single antibiotic is usually adequate. For patients who might be exhibiting signs of sepsis or for those who are immunocompromised, empirical therapy typically should include two antipseudomonal antibiotics to increase the likelihood that the choices will provide adequate antimicrobial coverage and potentially take advantage of antibiotic synergy. Antibiotic choice should be guided by antimicrobial susceptibilities. Extended-spectrum cephalosporins, aminoglycosides, carbapenems, aztreonam, and fluoroquinolones are reasonable antibiotic options. In children, more experience exists with extended-spectrum cephalosporins and aminoglycosides. Oral fluoroquinolones may be considered in situations with no systemic infection and an interest in providing nonparenteral therapy. Duration of appropriate antibiotic therapy should be at least 7 to 10 days. Longer duration of therapy may be needed in immunocompromised patients, presence of systemic infection, presence of a urinary catheter or other dwelling instrument, pyelonephritis, or patients with anatomic or functional abnormalities.

P. aeruginosa may be responsible for lower respiratory tract infections in neonates, infants, children, and adolescents in a variety of settings. The most common manifestations are involvement of the airways in patients with cystic fibrosis and health care–associated tracheitis or pneumonitis in intubated patients. *P. aeruginosa* also may be responsible for pneumonia in immunocompromised children, particularly those with neutropenia, and rarely as a cause of bacterial tracheitis after viral laryngotracheobronchitis.[42]

In patients with cystic fibrosis experiencing an exacerbation of pulmonary disease and in critically ill intubated patients in whom *P. aeruginosa* infection is suspected, combination therapy with a β-lactam antibiotic and an aminoglycoside is recommended as empirical treatment. Combination therapy has the potential for synergistic activity and has superior clinical efficacy in contrast to monotherapy.[142] Quinolones do not appear to be synergistic with either β-lactam antibiotics or aminoglycosides.[174] Quinolones could be used in postpubertal children as combination therapy when antibiotic resistance reduces the potential benefit of either the β-lactam or the aminoglycoside.[156] The choice of which β-lactam antibiotic and which aminoglycoside to use should be based on the patient's previous antibiotic experience and knowledge of the usual antibiotic susceptibility pattern in the patient's clinical environment. Once susceptibility testing results are known, at least two effective antibiotics should be included in the patient's regimen. The dose and pharmacotherapeutics of the chosen antibiotics should be optimized. If the patient fails to respond to appropriate antibiotic therapy, as evidenced by clinical deterioration,

acquisition of antibiotic resistance should be anticipated and additional bacterial cultures should be obtained; one or more of the newer antibiotics should be substituted pending additional susceptibility test results.

After years of antibiotic exposure, patients with cystic fibrosis commonly are infected with strains of *P. aeruginosa* resistant in vitro to achievable blood concentrations of many if not all of the common classes of antimicrobial agents. Moreover, penetration of aminoglycosides from blood into respiratory secretions is poor.[26] The administration of antibiotics by aerosolization, particularly the aminoglycosides through an endotracheal tube, provides much higher concentrations in respiratory secretions. This approach results in more rapid bacteriologic eradication, but clinical efficacy has varied across studies.[47] Administration of aerosolized aminoglycosides to patients with cystic fibrosis resulted in improvement in pulmonary function tests, decreased concentrations of *P. aeruginosa* in sputum, and no significant apparent toxicity. This aerosol treatment did not increase the isolation of *B. cepacia* complex, *Stenotrophomonas maltophilia*, or *Alcaligenes xylosoxidans;* however, isolation of *Candida albicans* and *Aspergillus* spp. increased.[49]

Aerosolized tobramycin may be used to yield concentrations in respiratory secretions in the range of 100 to 200 μg/mL. Some strains of *P. aeruginosa* resistant to blood concentrations of tobramycin may be susceptible to achievable concentrations in respiratory secretions. In vitro susceptibility testing of these organisms may be performed to determine the exact minimal inhibitory concentrations (MIC).[129,226] Limited data exist on the correlation of such in vitro test results and clinical outcome; therefore, in practice, such testing is not commonly performed. In addition to management of resistant *P. aeruginosa*, aerosolized tobramycin given over a prolonged period (>1 year) may have the potential to eradicate *P. aeruginosa* temporarily from cystic fibrosis patients who have newly acquired this organism.[268]

More recently, inhaled aztreonam has been shown to provide benefit to some patients with cystic fibrosis.[218,243,343] Inhaled administration of aztreonam can provide local concentrations of aztreonam in pulmonary mucus that is more than 100 times the MIC50. of the patient's *P. aeruginosa* isolates.[18] Confirmation of the efficacy of prolonged antibiotic aerosol therapy may prove valuable because recent data indicate a poor outcome in children with cystic fibrosis who acquire *P. aeruginosa* by the age of 7 years.[236] Although aztreonam is not approved for use in pediatric patients, inhaled aztreonam has recently been shown to improve lung function (improvements in FEV_1), health-related quality of life, and weight in patients with cystic fibrosis who are colonized with *P. aeruginosa*.[218,243,343] Reductions also occurred in bacterial density in sputum.[218,343] Inhalation of aztreonam had minimal effect of susceptibility of the patient's *P. aeruginosa* isolates to aztreonam after a course of treatment[18,242]; however, increases in susceptibility to tobramycin were observed.[242]

Increasing rates of respiratory and invasive infections with multidrug resistant *P. aeruginosa* in cystic fibrosis and immunodeficient patients, particularly those with malignancies, have resulted in the need to expand antimicrobial options, including reconsideration of older antibiotics. Although the use of polymyxin B and colistin (polymyxin E) has been superseded largely by less toxic agents, they may be useful in selected patients who are infected with strains resistant to the other agents. *P. aeruginosa* is almost always susceptible to these agents (*B. cepacia* complex organisms are resistant). Colistin is available as colistin sulfate, a topical agent or oral preparation (poorly absorbed from the gastrointestinal tract) and colistimethate sodium for parenteral administration. Colistin has retained antimicrobial activity against some multidrug-resistant gram-negative bacteria, including *P. aeruginosa*. During early use of colistin, high rates of nephrotoxicity dampened interest in the drug[97,103]; however, more recent studies have documented lower rates of nephrotoxicity.[261] Studies in adults have shown safety and efficacy in selected populations against *P. aeruginosa* and other multidrug-resistant gram-negative bacteria.*

In the United States, quinolone usage is limited to specific infections until after puberty because these antibiotics may bind cartilage and produce growth arrest. Fluoroquinolones are approved for use in patients younger than 18 years of age to treat complicated urinary tract infections, pyelonephritis, and postexposure treatment for inhalation anthrax. The information available from clinical trials in Europe suggests that ciprofloxacin and the other quinolones may not be as harmful in children as they are in other juvenile animal species.[69,293,294]

Among the quinolones, ciprofloxacin and levofloxacin are considered antipseudomonal and have been evaluated most often for the treatment of acute and chronic *P. aeruginosa* infection in adolescents and adults with cystic fibrosis.[158,281,319,323] Ciprofloxacin, which may be given orally or intravenously, proved to be effective, as judged by clinical scores and results of pulmonary function tests. Ciprofloxacin may be considered in selected children when the risks associated with the use of this antibiotic are outweighed by the potential benefits associated with its clinical efficacy. Such situations include the treatment of multiresistant strains of *P. aeruginosa* and the substitution of an oral quinolone to avoid long-term intravenous therapy requiring an indwelling catheter. If ciprofloxacin is used in a patient younger than 18 years of age for infections other than those for which it is approved, the balance of the risks and benefits of administering ciprofloxacin and alternatives should be explained to the patient and parents or guardians. Ciprofloxacin may be administered in a dosage of 15 mg/kg every 12 hours orally or 10 to 15 mg/kg twice per day intravenously. The oral dosage should not exceed 1000 mg/day in patients who weigh less than 40 kg or 1500 mg/day in patients who weigh more than 40 kg.

Determining the optimal antibiotic therapy for patients with cystic fibrosis may be problematic. Respiratory cultures often yield different colony morphotypes of *P. aeruginosa*. The various morphotypes may have significantly different antibiotic susceptibility patterns. It is common practice for laboratories supporting the

*References 31, 38, 120, 134, 169, 247, 275, 283.

management of patients with cystic fibrosis to individually test multiple morphotypes to include both mucoid and nonmucoid strains.

Antibiotic therapy for *B. cepacia* complex infection is challenging and should be guided by results of in vitro susceptibility testing. Unfortunately, *B. cepacia* is frequently resistant to many commonly used antipseudomonal antibiotic agents, particularly the aminoglycosides. Antibiotics that may have activity against *B. cepacia* include TMP-SMX, minocycline, ceftazidime, antipseudomonal penicillins, antipseudomonal quinolones, and carbapenems; meropenem has greater in vitro activity against *B. cepacia* than imipenem.[98] Typically, *B. cepacia* isolates from patients with cystic fibrosis are more antibiotic-resistant than isolates from other patient populations. Combination therapy with two or three antibiotics may be required to achieve a clinical response. Combinations of β-lactam agents with aminoglycosides might provide synergy clinically, even when the *B. cepacia* strain isolated is aminoglycoside-resistant. *B. cepacia* may be sensitive to minocycline.[189] Minocycline may be considered to have an adjunctive role in the management of *B. cepacia* infection in patients with cystic fibrosis.

The most active antibiotics against *B. pseudomallei* are imipenem, piperacillin-tazobactam, piperacillin, ceftazidime, ticarcillin-clavulanate, ampicillin-sulbactam, tetracycline, and chloramphenicol.[312] Piperacillin, ceftazidime, and imipenem are not bactericidal in vitro.[312] Ciprofloxacin seems to be of limited value because of a high rate of resistance.

For acute systemic melioidosis, ceftazidime 150 mg/kg/day divided every 8 hours or meropenem 60 mg/kg/day divided every 8 hours are preferred.[42] These medications are administered for 7 to 14 days. Eradication requires additional therapy with TMP-SMX, with 8 mg/kg/day of TMP, orally divided every 12 hours for 12 to 24 weeks.[42] Some eradication regimens might use amoxicillin-clavulanate with 90 mg/kg/day of amoxicillin, divided every 8 hours, instead of TMP-SMX, or may add doxycycline 4 mg/kg/day divided every 12 hours to the TMP-SMX. When third-generation cephalosporins have been used, cefoperazone and ceftazidime have shown greater activity against *B. pseudomallei* than have other third-generation cephalosporin agents. Ceftazidime was compared with chloramphenicol, doxycycline, and TMP-SMX for the treatment of severe melioidosis.[349] Ceftazidime in a dosage of 150 mg/kg/day intravenously in three divided doses every 8 hours was associated with a 50 percent lower overall mortality rate in contrast to that of other forms of therapy. These results suggest that ceftazidime combined with an aminoglycoside and sulfisoxazole now should be considered the treatment of choice for severe melioidosis. Soft tissue infections should be treated for 4 to 6 months with tetracycline in children older than 8 years, provided in a dosage of 50 mg/kg/day in four divided doses. In younger children, TMP-SMX, with 8 mg/kg/day of TMP and 40 mg/kg/day of SMX, in two divided doses may be used. Most penicillins are ineffective.[99,312] The duration of therapy must be guided by clinical and laboratory findings; therapy for 4 weeks to many months may be required in patients with osteomyelitis. Relapses are common occurrences and should be treated as one would treat the first episode.[61]

Chronic melioidosis can be treated with chloramphenicol over a period of many months or with tetracycline or doxycycline. TMP-SMX was recommended previously, but most strains currently are resistant.

Mechanisms of Antibiotic Resistance and In Vitro Susceptibility Testing

Antibiotic resistance is an important factor in management of patients with serious pseudomonal infections that do not respond to antibiotic therapy. *P. aeruginosa* shows intrinsic resistance to some antibiotics generally effective against enteric gram-negative rods. This is partly due to the relative impermeability of the outer membrane of *P. aeruginosa*. This membrane is a selective barrier to the uptake of antibiotics. The major porin channel of *P. aeruginosa*, OprF, has a limited number of large channels and other porins, including OprB and OPrD, and limits the rate of passage of molecules the size of antibiotics.[249] Aside from the importance of porin channels in resistance or reduced susceptibility to antibiotics, *P. aeruginosa* may show intrinsic resistance to a wide variety of antibiotic classes by the presence of multiple efflux pumps, particularly the resistance modulation systems MexAB-OprM and MexXY-OprM. Finally, upregulation and overexpression of the intrinsic, inducible chromosomal AmpC β-lactamase renders the organism resistant to first- and second-generation cephalosporins, as well as cefotaxime and ceftriaxone. Thus, the high level of intrinsic resistance to antimicrobial agents in *P. aeruginosa* is a combination of several mechanisms acting concurrently.[44,335]

Aside from intrinsic resistance, *P. aeruginosa* may acquire resistance genes by horizontal transfer from other bacteria by conjugation, transformation, or transduction, as well as by mutational events in the bacterial genome.[76] For example, *P. aeruginosa* may acquire resistance via acquisition of plasmid-mediated β-lactamases, including extended-spectrum β-lactamases such as the TEM, SHV, VEB, GES, and PER types of enzymes, and metallo-β-lactamases (carbapenemases) such as the IMP and VIM types of enzymes or aminoglycoside-inactivating enzymes (AAC [6′]-I and APH [3′]-II). Similarly, mutational events in the genome of *P. aeruginosa* may lead to clinical resistance. Hyperproduction of AmpC β-lactamase (encoded by the *ampC* gene) may result from a mutation in the *ampD* gene, whose protein product controls the activity of the AmpR regulator protein. Mutations in genes coding for antibiotic target enzymes such as DNA gyrase/topoisomerase II (*gryA* and *gyrB*) and topoisomerase IV (*parC* and *parE*) may yield enzymes with reduced fluoroquinolone-binding activity and clinical resistance. Furthermore, overexpression of the MexAB-OprM efflux pump as a result of a mutation in the *mexZ* gene may lead to clinical resistance to aminoglycoside, fluoroquinolone, and select antipseudomonal β-lactam antibiotics.[263,368]

The most clinically relevant β-lactamases produced by *P. aeruginosa* are chromosomally encoded Ambler class C cephalosporinases,[274] whose synthesis may be increased

on exposure to a number of β-lactam antibiotics (derepression of the *ampC* gene).[292] The propensity to induce *ampC* β-lactamase varies among the β-lactam antibiotics, with both cefoxitin and imipenem being strong inducers.[19,80,96] All antipseudomonal penicillins, cephalosporins (including cephamycins such as cefoxitin), and aztreonam are inactivated to varying degrees by the AmpC β-lactamase produced by *P. aeruginosa*, but cefepime and to a greater extent the carbapenems are relatively stable to inactivation.[234] *P. aeruginosa* strains harboring the *ampC* gene may produce only low levels of β-lactamase in vitro on initial isolation, and such strains may appear susceptible to β-lactam antibiotics on initial in vitro testing. Once patients colonized or infected with these strains are exposed to β-lactam antibiotics during therapy, induction of β-lactamase production may lead to emergence of resistance. For this reason, repeat in vitro susceptibility testing of additional clinical isolates of *P. aeruginosa* obtained after 48 to 72 hours of appropriate therapy is warranted.

Clavulanate and tazobactam are β-lactamase inhibitors effective against plasmid-encoded Ambler class A β-lactamases, including extended-spectrum β-lactamases found in *P. aeruginosa* and other gram-negative bacteria. However, these β-lactamase inhibitors are not only ineffective against the common AmpC β-lactamase of *P. aeruginosa*, but also are potent β-lactamase inducers. Use of these β-lactamase inhibitors will not enhance the activity of ticarcillin-clavulanate or piperacillin-tazobactam against *P. aeruginosa* and might actually increase the likelihood of emergence of resistant strains.

Whereas imipenem, meropenem, and doripenem resist the β-lactamases commonly produced by *P. aeruginosa*, resistance to carbapenems can result through the loss of an outer-membrane porin that allows carbapenems to enter *Pseudomonas*.[50] The permeability of other β-lactam antibiotics also may be reduced when this outer-membrane porin is lost. Although chemically distinct from imipenem or meropenem, fluoroquinolones such as ciprofloxacin may induce decreased permeability to both antibiotics.[266] Plasmid-mediated metallo-β-lactamases that confer resistance to imipenem have been described.[224,301,344] Fortunately, these metallo-β-lactamases are identified only rarely in *P. aeruginosa*.

Ciprofloxacin and levofloxacin are the most effective of the quinolones against *P. aeruginosa*. Alteration of the binding site of DNA gyrase and decreased penetration of ciprofloxacin through the *Pseudomonas* cell membrane can result in resistant strains.[96,199]

Tobramycin is the most active aminoglycoside against *P. aeruginosa*, and amikacin induces the lowest frequency of resistant strains. Resistance to aminoglycosides usually results from enzyme-mediated antibiotic modification.[90] The various aminoglycoside-modifying enzymes have different substrate affinities. Therefore, resistance to one aminoglycoside through aminoglycoside-modifying enzymes does not predict resistance to others necessarily. Resistance is less common to amikacin than to other aminoglycosides.[124,367] Aminoglycoside-modifying enzymes usually are coded by plasmid-mediated genes, but they occasionally can be coded by genes on the bacterial chromosome.[90] Plasmid-encoded resistance supports rapid transference among strains within an institution. *P. aeruginosa* also can become resistant to aminoglycosides by decreasing the intracellular uptake of aminoglycosides or by modification of intracellular ribosomal attachment.[83,96] These mechanisms of resistance generally cause cross resistance for all aminoglycosides.

In addition to antibiotic resistance, other clinical factors can adversely affect aminoglycoside activity against *Pseudomonas*. The acidic environment in tissue infected with *P. aeruginosa* can inactivate aminoglycosides.[36] Aminoglycosides may fail to reach therapeutic tissue levels because of poor penetration into bronchial secretions and lung tissue.[26] For patients with tracheitis (e.g., intubated patients) or endobronchial disease (e.g., cystic fibrosis), aminoglycosides and, less frequently, colistin have been administered by aerosol.[295] This route of delivery allows for greater availability of the antibiotic at the site of the infection, with enhanced safety because of negligible absorption into the systemic circulation. Doses of gentamicin and tobramycin of 2.5 to 8 mg/kg can be given safely by aerosol three times per day, with a maximum of 300 mg/dose. Resistance may emerge after prolonged courses.

Some studies have reported on the accuracy of automated or semiautomated antimicrobial susceptibility test systems as to the potential for reporting errors for susceptibility of *P. aeruginosa* to various antibiotics, particularly β-lactam agents.[77,165,284] The problem appears to be more pronounced with rapid systems that generate a susceptibility result in less than the 18- to 24-hour incubation period used in conventional testing. Such systems have difficulty in detecting resistance against β-lactam agents that may require a minimum time for expression of resistance to a level detectable by phenotypic methods relying on detection of growth. In general, more traditional antimicrobial susceptibility test systems, which include incubation for at least 18 to 24 hours, such as disk diffusion, broth or agar dilution, or epsilometer test (E-test), produce more reliable results. In one large multicenter study, the agar diffusion methods of disk diffusion and E-test performed acceptably in contrast to a reference broth microdilution method for both mucoid and nonmucoid isolates of *P. aeruginosa* from patients with cystic fibrosis.[48] In the same study, mucoid isolates were generally found to be more susceptible than nonmucoid isolates. This finding agreed with several other, but not all, studies. The clinical significance of these in vitro findings is difficult to interpret given that the mucoid phenotype is thought to be primarily associated with biofilms where antibiotic penetration is compromised. In fact, the role of routine in vitro antibiotic susceptibility testing in children with cystic fibrosis as it relates to clinical response and short-term outcomes has been questioned.[152] Not surprisingly, the role of in vitro antibiotic synergy testing for multidrug-resistant *P. aeruginosa* has also been questioned because of the lack of standardized testing methods and good outcome data.[1,117]

There are several recent Clinical Laboratory Standards Institute (CLSI)[71] changes to disk diffusion and MIC interpretative standards (MIC breakpoints) for susceptibility to *P. aeruginosa*, specifically affecting the

breakpoints for piperacillin, ticarcillin, piperacillin-tazobactam, and ticarcillin-clavulanate and breakpoints for the antipseudomonal carbapenem antibiotics—imipenem, meropenem, and doripenem. The MIC breakpoints for the antipseudomonal penicillin and penicillin and inhibitor combination antibiotics have been changed from the previous breakpoints of ≤64 μg/mL = susceptible (S) and ≥128 μg/mL = resistant (R) to ≤16 = S, 32 to 64 = intermediate (I), and ≥128 μg/mL or greater = R. This change was prompted by studies indicating that the likelihood of achieving blood levels of these drugs above 32 or 64 μg/mL for 50 percent of the time between doses was zero.[209] Indeed, some studies suggest that monotherapy for serious *P. aeruginosa* infection is often ineffective with organisms with such elevated MICs.[59,253] Similarly, the MIC breakpoints against *P. aeruginosa* for imipenem and meropenem have been changed from the previous breakpoints of ≤4 = S, 8 = I, and ≥16 μg/mL = R to ≤2 = S, 4 = I, and ≥8 μg/mL = R. The same revised breakpoints are applicable to doripenem. The revised and more conservative carbapenem breakpoints reportedly allow for better detection of "nonsusceptibility" among isolates of *P. aeruginosa*.

It is important to note that CLSI has published separate MIC breakpoints for other *Pseudomonas* spp. and nonfastidious, glucose-nonfermenting, gram-negative rods, as well as specific MIC breakpoints for *B. cepacia*, *B. pseudomallei*, and selected other related organisms.[70] In most cases, breakpoints are available only for a limited number of antibiotics and may not include disk diffusion breakpoints. In general, MIC methods are preferred for such organisms.

PREVENTION

Prevention of infection with pseudomonads depends in part on a continuous surveillance program of the hospital environment that is designed to identify and subsequently eradicate sources of pseudomonads as quickly as possible. Transmission of health care–associated *P. aeruginosa* can frequently be traced back to colonization of the health care institution's water distribution system. Biofilm colonization of faucets can be particularly problematic. However, eradication of *P. aeruginosa* from the water distribution system has not been successful even after using high water temperatures, copper and silver ionization, microfilters at faucets, or removal of colonized faucets. Because it is not possible to eradicate *P. aeruginosa* from the environment, other infection control measures, especially good hand hygiene and the use of sterile water to wash patients and patient supplies are needed. Pseudomonads can grow to a concentration of 10^6 organisms per milliliter in distilled water that appears to be perfectly clear. Growth of pseudomonads in distilled water, disinfectants, and medications is the factor most commonly incriminated in single-source outbreaks of *Pseudomonas* infection in hospitals. Prevention of the follicular dermatitis caused by *P. aeruginosa* contamination of whirlpools or hot tubs should be possible by maintaining the pool water at a pH of 7.2 to 7.8 and free allowable chlorine concentrations at 0.4 to 1.5 ppm.[54]

Outbreaks of *Pseudomonas* infection in newborn nurseries have been reported.[35] Generally, infection has been transmitted by the hands of personnel from washbasin surfaces and suction catheter rinse solution to the newborn infants. Strict attention to hand washing, particularly with a liquid iodophor hand washing agent before and between contact with newborn infants, may prevent or interdict epidemic disease. Growth of *Pseudomonas* on suction catheters can be prevented by rinsing the catheter in an acetic acid solution.

Daily replacement of all apparatus used for intravenous administration greatly reduces the hazard of extrinsic contamination by *Pseudomonas* and other gram-negative organisms. When intravenous administration is indicated, a small metal needle is preferable to a plastic catheter because these needles have been associated with a lower rate of septicemia and phlebitis.

Meticulous care is required in the preparation of solutions for total parenteral alimentation and in the insertion and care of catheters.

The risk for developing *Pseudomonas* infection in a burn patient also can be minimized by careful protective isolation and by the topical application of silver nitrate (0.5%) solution or 10 percent mafenide acetate cream. Débridement for removal of devitalized tissue is also imperative.

Pseudomonas infection of dermal abnormalities that communicate with the cerebrospinal axis can be prevented by careful evaluation and early surgical repair. Providing antibiotic prophylaxis of *Pseudomonas* urinary tract infection is difficult without a suitable oral antipseudomonal antibiotic for children. Identification and surgical correction of obstructive lesions of the urinary tract minimize or prevent the development of *Pseudomonas* infection of the urinary tract.

Cohorting plus isolation of patients with cystic fibrosis who are colonized with multiresistant strains of *P. aeruginosa* or *B. cepacia* has been suggested as a means of reducing nosocomial transmission of these organisms.[109] However, the proper manner of handling patients with these organisms has not been established. Any attempt to reduce transmission should be based on measures with proved efficacy and must also consider the potential consequences of strict isolation or segregation on this population, which spends so much time at health care facilities.

In patients with cystic fibrosis and certain immunocompromised patients, high rates of *P. aeruginosa* colonization and infection and ever-increasing antibiotic resistance render active or passive immunization (or both) against *P. aeruginosa* desirable. In the last 2 decades, an understanding of the human immune response to *P. aeruginosa* and the immune responses that may provide protection against infection or disease has increased considerably. Naturally occurring immunity generally is ineffective. Certain naturally generated antibodies may even be detrimental.[348] These antibodies may form antigen-antibody complexes that increase pulmonary inflammation and direct lung damage. Even if neutralizing antibodies could be administered passively or developed after vaccine administration, the large quantities of mucoid exopolysaccharide produced by *P. aeruginosa* may

mask many of the antigens targeted for antibody neutralization or opsonization.

Despite the previously mentioned difficulties, numerous investigations of candidates for *P. aeruginosa* vaccines are ongoing. Purified bacterial proteins, including flagellar antigen, outer-membrane proteins, lipopolysaccharide-O, several inactivated bacterial toxins, high-molecular-weight polysaccharide antigen and glycoconjugate, and killed whole-cell vaccine preparations, have been tested. Many of the candidate vaccines have been shown to be safe, immunogenic, and capable of generating protective immunity in various animal systems.[123] To date, evidence of protective efficacy in humans has not been established definitively for any of these vaccines. Some studies have demonstrated the efficacy of active immunization of burned patients with specific strains of *Pseudomonas* or the administration of hyperimmune globulin in the prevention of *Pseudomonas* septicemia.[5,167] *P. aeruginosa* vaccine also has been suggested as a possible method for preventing or delaying this disease in patients with acute leukemia or cystic fibrosis.[197,257]

The route of vaccine delivery may be important in creating the optimal immune response. Data from experimental animals suggest that vaccine antigens administered parenterally stimulate IgG and IgM antibodies and antigens administered orally induce IgA and IgG at mucosal surfaces. For patients whose disease occurs after mucosal colonization (e.g., cystic fibrosis), oral administration of a *P. aeruginosa* vaccine might be the preferred route of administration to develop the optimal immune response at the site of *P. aeruginosa* infection.

Purified bacterial proteins and lipopolysaccharide from *B. cepacia* are in the initial vaccine research and development stages. Whether these *B. cepacia* vaccine candidates will enter preclinical or phase I clinical trials is yet to be determined.

PROGNOSIS

The prognosis depends largely on the nature of the underlying disease process. Septicemia is the leading cause of death in children with leukemia; *Pseudomonas* is responsible for half of these deaths. Four variables independently influence the outcome of *Pseudomonas* septicemia: (1) the development of septic shock, (2) inappropriate antibiotic therapy, (3) granulocyte counts less than 500/mm,[5] and (4) the development of septic metastases.[24] Most deaths in children with cystic fibrosis are caused by pulmonary insufficiency. *Pseudomonas* can be recovered from the lungs of almost every one of these patients and, in many, has been responsible for their deaths.

CHAPTER 126

Stenotrophomonas (Xanthomonas) maltophilia

Carlos A. Sattler

Stenotrophomonas maltophilia is a gram-negative bacillus that previously belonged to the *Pseudomonas* and subsequently the *Xanthomonas* genus. In 1993, the new genus *Stenotrophomonas* was proposed, resulting in the most recent reclassification of this bacterium.[93] *S. maltophilia* is an opportunistic pathogen that has emerged as a significant cause of nosocomially acquired infection. It rarely is a cause of infection in healthy, immunocompetent children.

BACTERIOLOGY

S. maltophilia is an aerobic, nonfermentative, gram-negative bacillus that is lysine decarboxylase–positive and oxidase-negative, although recently, oxidase-positive isolates have been described.[15] In addition, key features that allow identification of *S. maltophilia* include oxidation of glucose and maltose, as well as a positive DNase reaction.[49] Optimal growth occurs at 35°C (95°F); on sheep

blood agar, colonies appear rough and lavender green and have a distinct ammonia-like odor. Morphologically, the organism is a straight bacillus, 0.7 to 1.8 μm long, that is motile by means of multiple polar flagella. It grows well on standard culture media, including blood agar and chocolate agar, as well as in broth blood culture systems, within the standard 5-day incubation period. Because of the hardy nature of this organism, standard collection, transport, and storage procedures are sufficient. The use of selective media such as MacConkey agar allows for *S. maltophilia* to be isolated from polymicrobial specimens, although for highly contaminated samples such as feces, the addition of antibiotics such as imipenem, vancomycin, and amphotericin B to the media should be considered.[68] New diagnostic techniques for the identification of *S. maltophilia* are being developed, but further experience with these methodologies is needed.[80,88]

EPIDEMIOLOGY

S. maltophilia is a free-living, ubiquitous organism; the natural habitats for it include water, soil, and plants. The ability to survive in an aqueous milieu has allowed *S. maltophilia* to occupy a niche in the hospital environment. It has been cultured from contaminated dialysis fluids[10] and intraocular rinsing solution,[60] as well as ventilators and other respiratory equipment,[30,69,101] and preoperative surgical brushes.[92] Several reports have linked nosocomial outbreaks of *S. maltophilia* to contamination of hospital water sources such as faucet aerators,[121] taps,[102] and sinks,[69] as well as disinfectant solutions.[124] Intestinal colonization with *S. maltophilia* has been described in hospitalized oncology patients with diarrhea and could represent a potential source of nosocomial infection.[4] Other reports have described cases of nosocomial cross infection occurring in neonatal and pediatric intensive care units.[45,54,73] In addition, cases of "pseudoinfection" caused by contamination of blood collection tubes have been described.[105]

Predisposing factors associated with colonization and infection by *S. maltophilia* include the presence of a severe, debilitating underlying illness, particularly malignancy; immune suppression (including human immunodeficiency virus infection); hematopoietic stem cell transplantation; exposure to broad-spectrum antibiotics (particularly to carbapenems, quinolones, or broad-spectrum cephalosporins); prolonged exposure to antibiotics; the presence of a central venous catheter; neutropenia; severe mucositis; prolonged hospital stay; stay in an intensive care unit; tracheostomy; mechanical ventilation; chronic obstructive pulmonary disease; or a combination of these factors.*

Among children, predisposing factors are similar to those found in adults.[104] Infection with *S. maltophilia* generally is hospital acquired.[46,104] Interestingly, a recent retrospective case-control study in children found that patients with *S. maltophilia* bloodstream infection were more likely to develop their infection in the home setting. However, almost all patients had a central venous catheter in place; thus, the cases represented health care–associated infections.[64] *S. maltophilia* is being isolated from clinical samples with increasing frequency.* This increase probably is related to advances in medical care that allow for a rise in the survival rate of severely ill patients, who are at highest risk for acquiring infection with this organism and who require more frequent use of invasive medical equipment, including indwelling lines, as well as broad-spectrum antimicrobials to which the organism is not susceptible.

PATHOPHYSIOLOGY

Like many pseudomonads, *S. maltophilia* is an organism with low virulence and limited invasiveness. An intact host immune system is an important deterrent to acquisition of a severe and even life-threatening infection; septicemia and death occur in patients with underlying debilitating illnesses. *S. maltophilia* elaborates a wide range of extracellular enzymes, including DNase, RNase, fibrinolysin, lipase, hyaluronidase, protease, and elastase, which may play a role in the pathogenesis of disease processes associated with *S. maltophilia*.[29] The pathogenesis of *S. maltophilia* infection also may be related to the development of cytotoxic activity.[41] In addition, *S. maltophilia* has been found to adhere to plastic materials, including intravenous catheters, and to produce biofilm that limits access to both phagocytes and antibiotics, properties that may account for the relatively high incidence of catheter-related bloodstream infections caused by this organism.[25,29,37] *S. maltophilia* is inherently resistant to several classes of antibiotics. Colonization with *S. maltophilia*, especially in the respiratory tract, is not an uncommon finding. In debilitated patients, exposure to broad-spectrum antimicrobials, many of which are ineffective against this bacterium, may allow overgrowth of colonizing organisms that subsequently gain access to sterile body sites and cause infection. Portals of infection include indwelling devices such as central venous catheters, peritoneal dialysis or urinary tract catheters, the respiratory tract, and the gastrointestinal tract.

CLINICAL MANIFESTATIONS

S. maltophilia once was regarded as a microorganism with very limited pathogenicity that was unlikely to cause infection except in the most debilitated patients.[46] However, the incidence as well as the severity of infection and the spectrum of clinical manifestations caused by this bacterium have increased. The most common site of isolation of *S. maltophilia* is the respiratory tract, particularly in hospitalized, mechanically ventilated patients. Attributing a causative role to *S. maltophilia* occasionally is difficult when the organism is isolated only from

*References 5, 6, 13, 14, 27, 36, 44, 82, 90, 91, 112, 117, 126

*References 5, 35, 70, 81, 85, 104.

respiratory secretions, particularly as part of a mixed culture. Most critically ill, mechanically ventilated patients have abnormal chest radiographs, and differentiating infectious from noninfectious infiltrates may be very difficult. Nonetheless, *S. maltophilia* has unequivocally been associated with pneumonia, which may be severe and which may occur in patients who are not receiving mechanical ventilation.[1,42,48] Occasionally, the pathogen may be associated with massive, fatal pulmonary hemorrhage in adult patients with malignant disease,[34] and it is a cause of ventilator-associated pneumonia.[78] In adults with pneumonia, the development of secondary bacteremia signals a grave prognosis.[35]

S. maltophilia bloodstream infections usually are catheter-associated.[11,69,71,86,116] In a series of 32 episodes of bacteremia in children, all were related to the presence of a central venous catheter, although in 10 episodes, the primary source was not the catheter.[104] In a series of 217 episodes of *S. maltophilia* bloodstream infections occurring in patients with cancer who had central venous catheters, secondary bacteremia generally occurred in patients who were neutropenic, had concurrent pneumonia, or were critically ill, and it was associated with a worse outcome in contrast to patients who had central venous catheter–related bacteremia.[11] Frequently, *S. maltophilia* is isolated as part of a polymicrobial bloodstream infection, particularly when the central venous catheter is the origin of the infection. In children, the severity of illness appears to be similar regardless of whether *S. maltophilia* is isolated in a monomicrobial or mixed blood culture.[104] Malignant disease is the most common underlying illness in patients with bacteremia, and many patients have concomitant neutropenia. Bloodstream infections caused by *S. maltophilia* can be severe. In a pediatric series, 31 percent of the patients initially were seen in septic shock, and the attributable mortality rate was 6.3 percent.[104] In another pediatric series of 32 episodes of bacteremia occurring in 31 children, the crude mortality rate was 40.6 percent.[125] However, the death rate associated with *S. maltophilia* bloodstream infection is, in general, higher in adults.[69,70,83,86]

S. maltophilia endocarditis is a rare occurrence. It has been associated with intravenous drug abuse and frequently occurs after replacement of a prosthetic valve.[7,57,87,127] Surgical therapy often is required, although cure with medical treatment alone has been reported. No cases of endocarditis caused by this organism in children have been reported.

Urinary tract infections caused by *S. maltophilia* almost invariably occur in patients with structural abnormalities of the urinary tract, indwelling urinary catheters, or underlying illnesses. Infection may be severe and associated with sepsis and septic shock.[114]

Skin and soft tissue infections caused by *S. maltophilia* have occurred in patients who have had work-related injuries and wounds contaminated with soil and plant material, such as occur in injuries associated with use of lawn mowers.[23,33,51] In the hospital setting, *S. maltophilia* frequently is cultured from wounds and surgical sites, although determining the clinical significance of this organism in children, particularly when it is isolated in mixed culture, often is difficult.[104] In adult patients with cancer, tender, erythematous nodular skin lesions have been described in association with *S. maltophilia* bacteremia and probably represent metastatic infectious foci.[115] Cases of metastatic soft tissue involvement, including nodular skin lesions and pyomyositis, in pediatric patients with bacteremia have also been described.[108,125] All of these patients had severe underlying diseases, particularly hematologic malignancies, associated with neutropenia. *S. maltophilia* bacteremia and sepsis as a complication in burn patients have also occurred.[75,110]

S. maltophilia has been implicated in the development of ocular infections, including conjunctivitis and keratitis in the setting of ocular surface compromise resulting from trauma, the use of soft contact lenses, or previous infection with human herpes simplex virus.[97] Endophthalmitis and scleritis occurring after ophthalmologic surgical interventions and trauma also have been described.[18,19,59,65,99]

Meningitis caused by *S. maltophilia* is an extremely rare occurrence and usually is nosocomial and associated with neurosurgical procedures and infection of intraventricular devices.[96] However, spontaneous meningitis in four infants was reported.[77,89,103]

S. maltophilia is the fourth most common organism isolated from the bronchial secretions of patients with cystic fibrosis, after *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Haemophilus influenzae*.[111] The incidence and prevalence of *S. maltophilia* isolated from the respiratory secretions of patients with cystic fibrosis are increasing.[26,67,100,107] *S. maltophilia* is recovered from the sputum of an estimated 12 percent of patients with cystic fibrosis in the United States and from as many as 25 percent of such patients in Europe.[100,118] The origin of the bacterium is uncertain; evidence suggests that it may be acquired both in the hospital and in the community.[27] Colonization may be transient or persistent, with chronic colonization occurring more frequently in older patients.[111] Case-control studies identified greater exposure to antipseudomonal antibiotics, oral ciprofloxacin, inhaled aminoglycosides, and oral corticosteroids, as well as more hospitalization days, and isolation of *Aspergillus fumigatus* from the sputum as risk factors for colonization with *S. maltophilia*.[32,79,107] Unlike with *Burkholderia cepacia* infection, no evidence of patient-to-patient transmission of *S. maltophilia* has been found, nor does the organism appear to be associated with rapid deterioration of pulmonary function in patients with cystic fibrosis.[31,52] The clinical significance of isolation of *S. maltophilia* from the sputum of patients with cystic fibrosis and its role in the deterioration in lung function are unclear. Its presence may represent more a marker of severe, advanced disease than causally related respiratory deterioration.[28,53] However, recent data suggest that chronic infection with *S. maltophilia* is an independent risk factor for pulmonary exacerbation,[120] but chronic infection does not appear to affect subsequent lung function recovery.[119] Cases of *S. maltophilia* bacteremia have been rarely reported in patients with cystic fibrosis.[66]

Other infections caused by *S. maltophilia* include peritoneal catheter exit-site infections and peritonitis in

patients undergoing peritoneal dialysis,[24,106] as well as cholangitis,[94] osteochondritis,[8] mastoiditis,[58] bursitis,[95] sinusitis,[56] liver abscess,[98] osteomyelitis,[72] and necrotizing ulcerative gingivitis.[84]

DIAGNOSIS

The diagnosis of infection is established by isolating the organism from normally sterile sites in the presence of a compatible clinical picture. However, growth of *S. maltophilia* from normally sterile samples actually may represent an episode of pseudoinfection caused by the ability of this organism to contaminate and survive in hospital equipment such as blood collection tubes and antiseptic solutions. Because *S. maltophilia* is a common colonizer of hospitalized patients, isolation from nonsterile sites such as sputum or wounds is more difficult to interpret, particularly when the organism is isolated in mixed culture. Because nosocomial outbreaks have been reported, isolation of *S. maltophilia* from other patients in a hospital setting should alert the physician to the possibility of *Stenotrophomonas* infection. Infection control offices should be notified after the organism has been isolated.

Occasionally, *B. cepacia* is misidentified as *S. maltophilia*, especially in patients with cystic fibrosis.[12] *S. maltophilia* is oxidase-negative and DNase-positive. These tests should be repeated when identification of the organism is in doubt. Because of the serious clinical implications of misidentification in this group of patients, molecular analysis of the isolates should be considered if results remain uncertain.[123]

TREATMENT

Providing antibiotic therapy for *S. maltophilia* is difficult for several reasons. This organism displays multiple intrinsic resistance determinants that confer broad antibiotic resistance, including resistance to β-lactam antibiotic agents.[22] Mechanisms of resistance include the production of two chromosomally encoded, inducible β-lactamases designated L1 and L2. The former is a β-lactamase inhibitor–resistant metalloenzyme that hydrolyzes a broad range of β-lactam antibiotics, including carbapenems such as imipenem and meropenem. L2 is a cephalosporinase and, unlike L1, is susceptible to β-lactamase inhibitors.[29] Other mechanisms of resistance include reduced antibiotic uptake, the main mechanism providing aminoglycoside resistance, and an antibiotic efflux system that confers multidrug resistance.[3,129] Resistance to trimethoprim-sulfamethoxazole mediated by mobile genetic elements *sul1* and *sul2* has recently been reported.[109] In addition, in vitro antibiotic susceptibility testing is plagued by numerous methodologic problems. Several factors, including the time of incubation and the composition of the medium, affect the interpretation of test results. Furthermore, poor reproducibility among different testing methods has been described.[16,55] The Clinical and Laboratory Standards Institute (CLSI) has established standards for antibiotic susceptibility testing, including testing by both disk diffusion and broth or agar dilution (minimum inhibitory concentration [MIC] evaluation).[21] For the disk diffusion method, CLSI recommends testing only trimethoprim-sulfamethoxazole, levofloxacin, and minocycline. In the case of broth or agar dilution, CLSI recommends testing trimethoprim-sulfamethoxazole (susceptible: ≤2/38 μg/mL; resistant: ≥4/76 μg/mL), ceftazidime (susceptible: ≥8 μg/mL; intermediate: 16 μg/mL; resistant: ≥32 μg/mL), chloramphenicol (susceptible: ≤8 μg/mL; intermediate: 16 μg/mL; resistant: ≥32 μg/mL), levofloxacin (susceptible: ≤2 μg/mL; intermediate: 4 μg/mL; resistant: ≥8 μg/mL), minocycline (susceptible: ≤4 μg/mL; intermediate: 8 μg/mL; resistant: ≥16 μg/mL), and ticarcillin-clavulanate (susceptible: ≤16/2 μg/mL; intermediate: 32/2 to 64/2 μg/mL; resistant: ≥128/2 μg/mL). Regardless, no controlled clinical studies have determined the most effective antibiotic regimen or duration of treatment.

Antibiotic susceptibility studies and clinical observation suggest that the most active antibiotic against *S. maltophilia* is trimethoprim-sulfamethoxazole, and most authorities agree that it is the drug of choice. However, it is bacteriostatic—a property that may have clinical implications in immunosuppressed patients. In addition, resistant strains are being reported with increasing frequency,[2,83,113] although this is not a uniform finding.[76] Other antibiotics that have shown in vitro activity include ticarcillin-clavulanate, doxycycline, minocycline, and colistin, although clinical experience with the latter three drugs is limited.[29,38,39,62] The activity of early fluoroquinolones such as ciprofloxacin and ofloxacin varies widely, and emergence of resistance during treatment has been reported.[20] Newer quinolones, including levofloxacin and gatifloxacin, appear to have better activity in vitro against *S. maltophilia*,[40,63,74,122] but their activity decreases against multiresistant strains, and the development of resistance during the course of treatment has been described.[9] In addition, geographic variations in antibiotic resistance rates have been reported.[43] Tigecycline is emerging as a potential therapeutic option for *S. maltophilia*. However, clinical experience, particularly in children, is limited, and the proportion of susceptible isolates varies across studies.[61,39,62,50]

Bloodstream infections can be severe, particularly in immunosuppressed patients. Combination antibiotic therapy with trimethoprim-sulfamethoxazole and ticarcillin-clavulanate for bloodstream infections by isolates that are susceptible has been advocated by some authorities and is supported by in vitro pharmacodynamic model data.[86,113,128] Other combinations have shown varying efficacy and correlation between in vitro and in vivo findings, which have not always been consistent.[29] In cases of catheter-related bloodstream infection, removal of the catheter has been associated with improved outcome, in some circumstances irrespective of the appropriateness of antibiotic therapy, and should be considered for severely ill patients.[17,35,104,126] Nonetheless, successful treatment without removal of the catheter[86] as well as an association of inappropriate antibiotic therapy and death,[83] has been described. In cases of serious infection such as bacteremia or severe pneumonia, combination antibiotic therapy should be considered when in vitro and in vivo evidence

suggests that rapid emergence of resistance may occur during treatment.[47]

Appropriate management of patients from whom *S. maltophilia* is isolated from nonsterile sites, particularly in mixed culture, is not always clear because some isolates may represent colonization or contamination of the sample. In a pediatric study describing nonrespiratory infections in children, 6/16 patients with *S. maltophilia* that was cultured from sites other than the bloodstream were treated with antibiotics not active in vitro, and 5 of these children were "cured."[104] Nonetheless, in adults, *S. maltophilia* has been associated unquestionably with severe infection at sites other than the bloodstream and death caused by *S. maltophilia* infection has been associated with inappropriate initial antibiotic therapy.[90]

SUBSECTION 5
GRAM-NEGATIVE COCCOBACILLI

CHAPTER 127

AGGREGATIBACTER ACTINOMYCETEMCOMITANS

Suzanne Whitworth • Richard F. Jacobs

Aggregatibacter actinomycetemcomitans, formerly *Actinobacillus actinomycetemcomitans*, is a fastidious, non–spore-forming, nonmotile, facultatively anaerobic gram-negative coccobacillus that frequently complicates actinomycosis caused by *Actinomyces israelii*. In addition to being associated with actinomycosis, it has been implicated as a pathogen in periodontal disease and is part of the oral flora. Infection by this bacterium often is not resolved by the normal host, possibly because of inefficient phagocytosis and the weak oxidative burst response of neutrophils.[10] In addition, the bacterium has several virulence factors, including induction of apoptosis and tissue destruction.[5] *A. actinomycetemcomitans* is characterized by slow growth in culture and a requirement for incubation in an atmosphere enhanced with carbon dioxide.[7] Other bacterial species concomitantly isolated in human actinomycosis are *Eikenella corrodens*, *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus*, *Streptococcus*, and members of the family Enterobacteriaceae.

A. actinomycetemcomitans is a pathogen in at least 30 percent of actinomycotic infections.[7] Failure to recognize this organism and treat it adequately has resulted in clinical relapse and deterioration in patients infected with actinomycosis.[8,16] Severe forms of periodontitis, particularly localized aggressive periodontitis, also are associated with this pathogen, and studies have shown that it is related strongly to children in the pubertal age group.[1,12] It is characterized by loss of attachment of bone around the permanent incisors and permanent molars, which occurs rapidly. Treatment consists of local débridement and antibiotic therapy, usually metronidazole alone or in combination with amoxicillin. *A. actinomycetemcomitans* also is an important pathogen in Papillon-Lefèvre syndrome, an autosomal recessive disorder characterized by prepubertal periodontitis and palmar-plantar hyperkeratosis.[11] Additionally, it is one of the HACEK (HACEK includes *Haemophilus aphrophilus*, *Cardiobacterium hominis*, *E. corrodens*, and *Kingella kingae*) organisms that have a propensity for infecting heart valves. The endocarditis caused by this organism usually is insidious, with fever occurring in fewer than 50 percent of cases.[7] This organism has been reported to cause pericarditis, meningitis, brain abscess, parotitis, synovitis, osteomyelitis, urinary tract infection, pneumonia, and empyema.[7] Cases of endophthalmitis[2,14] and cavernous sinus infection also have been reported, as well as facial cellulitis.[6,15] "In recent years there has been increasing evidence of the potential association between periodontal and cardiovascular diseases. Periodontitis may be an independent risk factor for cardiovascular disease. A recent study revealed the presence of *A. actinomycetemcomitans* by PCR in atheromatous plaques obtained from carotid endarterectomies."[4]

A. actinomycetemcomitans can be cultured on blood and chocolate agar but grows poorly on MacConkey agar. Cultures require incubation in an enhanced carbon dioxide atmosphere. Growth of the organism in a blood culture may take as long as 9 days in patients with endocarditis, and thus cultures should be held longer. On Gram stain, the organism appears coccoid to coccobacillary. Molecular techniques based on nonamplification nucleic acid probes or on polymerase chain reaction can provide rapid and accurate identification of *A. actinomycetemcomitans*.[13] Because of the frequency of coinfection with this organism in cases of actinomycosis, attempts always should be made to isolate this organism in these patients.

A. actinomycetemcomitans is susceptible to the newer cephalosporins, rifampin, trimethoprim-sulfamethoxazole, aminoglycosides, quinolones, tetracycline, azithromycin, and chloramphenicol. It also is susceptible to penicillin and ampicillin in vitro, but test results do not necessarily correlate with clinical outcome. Vancomycin, erythromycin, and clindamycin have very little activity against this organism. Treatment of aggressive periodontal disease consists of local débridement and antibiotic therapy. Metronidazole and amoxicillin appear to be effective in suppressing *A. actinomycetemcomitans* to below the level of detection.[3] Endocarditis caused by this organism has been treated successfully with a combination of ampicillin and gentamicin.[9] Cefotaxime or ceftriaxone also is acceptable.

CHAPTER 128

BRUCELLOSIS

Edward Young

Brucellosis is a disease of animals (zoonosis) that is transmittable to humans.[91] Humans are accidental hosts, and human-to-human transmission is rare.[106] Brucellosis is distributed worldwide, and it is estimated that 500,000 human cases occur annually.[38,94] Programs to eradicate the disease in animals have reduced the incidence of human infection in many countries; however, brucellosis remains enzootic in large parts of the world.[144] Once considered rare in childhood, it is now recognized that persons of all ages are susceptible, especially in areas where *Brucella melitensis* is endemic.[128]

HISTORY

Brucellosis was one of many indistinguishable fevers until 1859 when J.A. Marston, a Royal Army Medical Corps (RAMC) physician, provided the first accurate description of the disease among troops stationed on Malta during the Crimean War. He also noted that "…when this form of fever attacks children, (which it frequently does), it is apt to leave behind it an enlarged condition of the spleen, difficult to remove."[76] During the 19th century, brucellosis was known by various names, including Mediterranean fever, Malta fever, and undulant fever.[87] Although the disease caused considerable morbidity and mortality in British military personnel stationed throughout the Mediterranean, the cause was not immediately apparent. In 1886, David Bruce, another RAMC surgeon, isolated a microorganism from spleen tissue of victims of Malta fever.[22] Termed *Micrococcus* (later renamed *Brucella*) *melitensis*, the organism could be found in the blood, urine, and feces of Malta fever patients. Between 1904 and 1907, Bruce headed the Mediterranean Fever Commission that studied aspects of the disease in Malta. It was Themistocles Zammit, a Maltese physician working with the Commission, who first identified native goats as the reservoir of brucellosis and their unpasteurized milk as the vehicle of transmission to humans.[135] When fresh goat's milk was replaced with tinned condensed milk in the military mess, the incidence of brucellosis among military personnel declined precipitously.[122] In 1897, Almroth Wright applied the newly devised agglutination assay to the serologic diagnosis of Malta fever.[139]

Unlike *B. melitensis* that was initially isolated from human tissue, other *Brucella* species were recognized for the disease they caused in animals. In 1897, Bernhard Bang, a Danish veterinarian, isolated the "abortion bacillus" (later *Brucella abortus*) from placental tissue of cattle suffering contagious abortions.[18] *Brucella suis* was isolated from swine around 1914 by Jacob Traum at the Bureau of Animal Industry.[60] In 1918, the bacteriologist Alice Evans finally recognized the relatedness of these disparate bacteria.[48] After Evan's work was confirmed, K.F. Meyer and E.B. Shaw proposed the name *Brucella* for the genus to honor Bruce.[57]

Additional *Brucella* species were isolated from sheep *(B. ovis)* and from desert wood rats *(B. neotomae)*, but neither has been linked to disease in humans. In 1966, Carmichael[26] identified *Brucella canis* as a cause of abortions in kennel-bred dogs; however, it appears to be a rare cause of infection in humans.[136] Recently, previously unrecognized *Brucella* species have been recovered from marine mammals.[21,55,62] Tentatively named *Brucella cetaceae* (dolphin and porpoise isolates) and *Brucella pinnepediae* (seal isolates), their role as human pathogens remains to be clarified.[31,77,116] Another novel strain of *Brucella* was recently isolated from a woman with an infected breast implant and was tentatively named *Brucella inopinata*.[40,137]

ETIOLOGY

The brucellae are small, fastidious, nonmotile, non–spore-forming gram-negative coccobacilli that lack native plasmids. The outer cell membrane resembles other gram-negative bacilli with a dominant lipopolysaccharide (LPS) component. Their metabolism is oxidative, and all strains are aerobic. Some strains require carbon dioxide for growth, especially for primary isolation. Brucellae are always catalase positive, but oxidase activity varies among biovars. Most strains reduce nitrate to nitrite, but some do not. Production of hydrogen sulfide also varies, as does urease activity. A variety of media support the growth of brucellae, including chocolate, trypticase soy, and serum dextrose agars. Growth in vitro is characteristically slow and when brucellosis is suspected the cultures should not be discarded before 28 days.

Brucellae belong to the α2 subdivision of the Proteobacteria phylogenetically related to plant pathogens and symbionts such as *Agrobacterium* and *Rhizobium* and to intracellular animal parasites such as *Bartonella* and *Rickettsia*.[32] On the basis of DNA-DNA hybridization and genome sequencing, the genus *Brucella* comprises a single species.[41,58,95] Despite genetic homology greater than 90 percent, the *Brucella* nomenspecies show a remarkable preference for certain natural hosts. Consequently, the traditional nomenspecies classification is retained for epidemiologic purposes (Table 128-1).

EPIDEMIOLOGY

Historically in the United States brucellosis was linked to the livestock industry and *B. abortus* was the predominant species causing human illness. Farmers, ranchers, abattoir workers, and veterinarians were at highest risk for infection, usually through direct contact with infected animals. With the virtual elimination of bovine brucellosis by way of test-and-slaughter and immunization of susceptible cattle, the epidemiology of brucellosis changed, especially in states that border Mexico. *B. melitensis* replaced *B. abortus* as the major cause of human disease, and foodborne transmission replaced direct contact with animals as the primary mode of infection.[28,131] On the Mexican border, human brucellosis occurs at a rate eight times above the national average, and unpasteurized goat's milk cheese is a common vehicle of transmission.[46,144,149] Human infection caused by *B. suis* has traditionally been an abattoir-associated infection, but in recent years the hunting of feral swine has become a risk when hunters are contaminated with the blood of infected animals.[24,124] Personnel working in clinical or research laboratories are also at risk, and brucellosis continues to be the most commonly reported laboratory-associated bacterial infection.[102,140]

Brucellosis once was thought to be uncommon or mild in children, but susceptibility now is recognized in persons of all ages.[112-114] Conditions for the transmission of brucellosis from animals to humans vary among countries and cultures. Where farm animals traditionally are raised in the home, contact with children occurs frequently. Moreover, foodborne infection is not limited to any age or sex and can occur without direct contact with animals. Childhood brucellosis occurs more commonly in locations where *B. melitensis* is enzootic, and multiple cases often occur within families.[11,74,147]

The clinical manifestations of brucellosis in children do not differ from those in adults, although unfamiliarity with the disease can delay the diagnosis.[7,27,29,126] Human-to-human transmission of brucellosis is rare, but evidence for venereal transfer has been documented.[106,123] Rare cases associated with blood or bone marrow transplantation have been reported.[2,5,10] Interestingly, few cases of brucellosis have been reported in patients infected with the human immunodeficiency virus.[84]

Spontaneous abortion is a common manifestation of brucellosis in animals where brucellae localize within the reproductive organs of both sexes. Brucellosis in pregnant women can lead to abortion if unrecognized and untreated.[104] In a retrospective study from Saudi Arabia, intrauterine death and spontaneous abortion occurred in 46 percent of 92 women with brucellosis.[67] This rate was significantly higher than the rate of spontaneous abortion in women without brucellosis. When diagnosed early, pregnant women can be treated successfully without compromising their ability to carry to term or to conceive again.[68] On rare occasions, transplacental transmission can lead to neonatal brucellosis.[85]

TABLE 128-1 **Nomenspecies Classification of *Brucella* spp.**

Species	Biovars	Natural Hosts	Pathogenicity for Humans
B. abortus	1-6, 9	Cattle, other Bovidae	Yes
B. melitensis	1-3	Goats, sheep	Yes
B. suis	1-3	Swine	Yes
	4	Reindeer, caribou	Yes
	5	Rodents	Yes
B. canis	—	Dogs, other canines	Yes
B. neotomae	—	Desert wood rats	No
B. ovis	—	Sheep	No
*B. maris**			
*B. pinnipediae**		Pinnipeds	?
*B. cetaceae**		Cetaceans	?
*B. inopinata**		?	? (single isolate)

*Tentative designations.
?, still unresolved.

PATHOGENESIS

The incubation period for brucellosis varies, but symptoms generally appear within 2 to 3 weeks after infection. Disease caused by *B. melitensis* and *B. suis* tends to be

more severe than illness due to *B. abortus* or *B. canis*.[131] Morbidity can be considerable, but death occurs in only about 1 percent of cases, usually from complications such as neurobrucellosis or endocarditis.[145] Although no racial or genetic differences in susceptibility are known in humans, innate immunity has been demonstrated in various animals.[45]

The brucellae lack the usual virulence factors of other bacteria. Lipopolysaccharide (LPS), the immunedominant antigen of the cell wall, appears to be the principal mediator of pathogenesis of brucellosis.[25] Although 10 to 100 times less toxic than conventional enterobacterial endotoxins such as *Escherichia coli*, brucella LPS functions through the same Toll-like receptor 4 (TLR4) pathway and contributes to the organism's ability to survive and replicate within naïve mononuclear phagocytes.[71] By mechanisms not yet fully understood, the smooth LPS of the organism impairs host complement-mediated killing, blocks phagosome-lysosome fusion, impairs inflammatory cytokine expression, and inhibits the production of nitrogen intermediates to undergo a respiratory burst.[25] Although humoral antibodies play some role in resistance to infection, the principal mechanism of recovery involves cellular immunity.[115] Intracellular killing of brucellae occurs when macrophages become "activated" by specifically committed $CD4^+$ and $CD8^+$ T lymphocytes. This T-helper-1 (Th1) response involves cytokines, including interferon-gamma, interleukin-2, and tumor necrosis factor.[141]

CLINICAL MANIFESTATIONS

The spectrum of human brucellosis ranges from subclinical (diagnosed by serology) to chronic (characterized by recurrent symptoms over many years).[148] The disease is characterized by a plethora of nonspecific somatic complaints, such as fatigue, anorexia, nausea, weight loss, sweats, and depression. In contrast, there is a paucity of physical findings, notably fever and occasionally hepatosplenomegaly. The infection can involve any organ or organ system of the body. Sometimes symptoms related to a single organ predominate, in which the disease is termed *localized*.[35] Not unexpectedly, localization often involves organs rich in elements of the reticuloendothelial system.

Osteoarticular complications are the most frequent localized manifestations of brucellosis, and in children symptoms of monoarticular arthritis involving the hips, knees, ankles, and sacroiliac joint predominate.[19,128,130,152] Spondylitis, osteomyelitis, and inflammatory arthropathy have also been described but occur less often in children than adults.[36,118] Despite advances in imaging techniques, serology and culture remain important for diagnosis.[63]

Neurobrucellosis comprises a variety of nervous system complications, including meningitis/encephalitis, myelitis, radiculitis, peripheral and cranial neuropathies, and demyelinating syndromes.[51,56,78,109,133] Vasculitis is common,[150] and rare cases of brain abscess and intracerebral granuloma can mimic a neoplasm of the central nervous system.[47,110] Although the majority of patients complain of headache and weakness, direct invasion of the central nervous system occurs in less than 5 percent of cases.[20,86] Analysis of cerebrospinal fluid (CSF) in cases of *Brucella* meningitis reveals a lymphocytic pleocytosis, elevated protein levels, and normal or low glucose levels. Organisms are rarely seen on Gram stain or cultured from CSF; however, antibodies to *Brucella* are present and their finding in CSF is diagnostic.[12] When available, polymerase chain reaction (PCR) assay on CSF can also confirm the diagnosis.[34]

Gastrointestinal complaints are common in uncomplicated brucellosis and include anorexia, nausea, vomiting, abdominal discomfort, and weight loss.[83,113] Rare cases of ileitis,[97] colitis,[64,125] and peritonitis[3] have been reported. As the largest organ of the reticuloendothelial system, the liver is likely always involved in brucellosis even though transaminase levels are only mildly elevated and can be normal.[35,72] Rarely, acute hepatitis occurs with hepatic enzyme levels resembling viral hepatitis.[4] The liver histology in patients infected with *B. abortus* is characterized by epithelioid granulomas indistinguishable from sarcoidosis.[121] In contrast, infection with *B. melitensis* can result in a spectrum of lesions ranging from diffuse hepatitis to granulomas.[142,145] Infection with *B. suis* (and *B. melitensis*) can also result in a suppurative abscess that may become chronic.[17,37,134]

Genitourinary tract involvement usually presents as orchitis or epididymo-orchitis and can be mistaken for testicular cancer.[59,89] Rare cases of interstitial nephritis, membranous nephropathy, and glomerulonephritis also have been reported.[151]

Respiratory tract localization of brucellosis is reported in about 7 percent of cases.[90,93,129] Lung lesions attributed to *Brucella* include hilar adenopathy, lobar pneumonia, lung nodules, pleural effusion, and thoracic empyema.[73] Pleural fluid adenosine deaminase levels may be elevated but are difficult to distinguish from tuberculosis.[43]

Cardiovascular lesions of brucellosis include endocarditis, myocarditis, pericarditis, and aneurysms of the aorta and cerebral blood vessels.[100] Both native and prosthetic valve endocarditis have been described, with the aortic valve involved most often.[42,61] Delays in making a diagnosis can result in life-threatening complications, such as valve rupture, myocardial abscess, and sinus of Valsalva fistulas. Treatment of *Brucella* endocarditis generally requires the combination of antibiotics plus valve surgery.[66,111]

Ocular lesions, most notably uveitis, have been described in patients with brucellosis. Other eye lesions that have been reported include endophthalmitis, optic neuritis, episcleritis, nummular keratitis, and chorioretinitis. The pathogenesis of some of the lesions is a matter of conjecture because brucellae are rarely isolated from the eye.[65,103,127]

Cutaneous lesions attributed to brucellosis include contact dermatitis, rashes, abscess, and vasculitis.[81,82] On occasion, brucellae have been cultured from subcutaneous papules[74] and from abscesses.[101]

Hematologic abnormalities such as anemia, leukopenia, and thrombocytopenia are common in the course of brucellosis.[30,39] These changes are generally mild and

resolve promptly with antimicrobial therapy. On occasion, thrombocytopenia can be severe, resulting in hemorrhage into the skin and from mucosal sites.[150] The etiology of this complication is likely multifactorial, including hypersplenism, disseminated intravascular coagulation, bone marrow suppression and hemophagocytosis, and immune mechanisms.

DIAGNOSIS

The symptoms of brucellosis are nonspecific; therefore, the importance of obtaining a detailed history including occupation, avocations, travel, animal exposure, and food habits cannot be overemphasized. Routine laboratory tests are generally not helpful, but characteristic hematologic findings (normal or low white blood cell count) can suggest the possibility of brucellosis.[8]

A definitive diagnosis of brucellosis is made by isolating a specific species of *Brucella* from blood, bone marrow, or other tissue. The rate of positive blood cultures varies from 15 to 70 percent depending on the methods used and the period of in vitro incubation.[54,108] Bone marrow culture has been reported to be more sensitive than blood cultures prior to the introduction of newer isolation techniques.[44,80] Nucleic acid amplification tests using a variety of gene sequences are now being applied with some success to the rapid diagnosis of brucellosis.[6,53,88,99,138]

In the absence of bacteriologic confirmation, a presumptive diagnosis can be made by measuring the titer of specific antibodies in serum.[143] Human brucellosis is characterized by an initial production of IgM antibodies followed by a switch to IgG synthesis within the second week of infection. Treatment results in a gradual decline in both antibody isotypes; however, the persistence of IgG antibodies is associated with relapse or chronic infection.[96] Consequently, the pattern of immunoglobulin isotypes is important to differentiate active from treated disease.[50,143] This is accomplished by performing the serum agglutination test (SAT) in tandem with 2-mercaptoethanol (2ME) (or dithiothreitol DTT); the latter are disulfide-reducing agents used to block agglutinability by IgM while preserving agglutination by IgG.[23,143] Alternatively, a more direct way to measure IgM and IgG antibodies is the indirect enzyme-linked immunosorbent assay (ELISA) employing anti-IgM and anti-IgG conjugates.[75,79] Because of problems with commercial IgM enzyme assays, the Centers for Disease Control and Prevention recommends that positive ELISA results be confirmed by agglutination.

Most serologic tests for brucellosis employ smooth lipopolysaccharide (S-LPS) that is capable of detecting antibodies to all smooth species *(B. abortus*, *B. melitensis*, *B. suis)*. Because *B. canis* is naturally rough (lacks S-LPS), antibodies to this organism require a test using antigen prepared from a rough species *(B. canis* or *B. ovis)*.[98] In addition, a variety of other cell wall or cytoplasmic proteins have been studied as potential serodiagnostic antigens[52] but none has proven to be superior to LPS-based assays. Recently, a latex agglutination assay using S-LPS has been shown to be simple to run, to be rapid, and to have good sensitivity and specificity.[1]

TREATMENT

Antimicrobial therapy lessens morbidity, shortens the course of illness, and reduces the incidence of complications of brucellosis.[146] A variety of drugs are active against *Brucella* spp., but the results of in vitro sensitivity tests do not always correlate with clinical effectiveness. Because the rate of relapse with single-drug therapy is high, successful treatment requires combination therapy for a prolonged time.[119,146] The tetracyclines remain the most effective antibiotics against brucellae with minimal inhibitory concentrations less than 1 μg/mL. In vitro killing of brucellae by numerous antibiotics can be enhanced by the addition of an aminoglycoside (streptomycin or gentamicin).[107] Traditionally, the combination of tetracycline administered for 6 weeks plus streptomycin given for 2 to 3 weeks provided the highest cure rates in patients with brucellosis.[13] Currently, the preferred regimen is doxycycline 200 mg/day given orally for 45 days plus gentamicin 5 mg/kg/day as a single daily intramuscular dose for the first 7 to 10 days.[14,105,117]

Rifampin also shows good in vitro activity against *Brucella* spp., and in 1986 the World Health Organization recommended the combination of oral administration for 45 days of doxycycline 200 mg/day plus rifampin 600 to 900 mg/day as the treatment of choice. Although this regimen has been used successfully, subsequent studies have shown the superiority of the combination of doxycycline plus an aminoglycoside.[16,120]

Children older than 8 years can be treated similar to adults.[132] Because tetracycline is contraindicated for children younger than age 8 years and for pregnant women, alternative treatments have been sought. Trimethoprim-sulfamethoxazole (TMP/SMX, cotrimoxazole) in a fixed combination of 80 mg TMP/400 mg SMX twice daily for 45 days plus gentamicin 5 mg/kg/day as a single daily dose for 7 days has yielded satisfactory results.[113] Alternatively, the combination of TMP/SMX plus rifampin 15 mg/kg once daily administered for either 6 or 8 weeks gave comparable results.[105] Similarly, pregnant women can be treated successfully with TMP/SMX plus rifampin without adverse drug effects in the newborn.[67]

The quinolones are active against *Brucella* spp. in vitro, but the minimal inhibitory concentration values vary for each compound and, to some extent, for *Brucella* isolates[49]; in clinical practice, however, the results have been disappointing.[69,70,146] Consequently, quinolones are not recommended as monotherapy for treating brucellosis and their role in combination therapy awaits well-designed clinical trials.

The optimal treatment of complications of brucellosis such as meningitis and endocarditis has not been defined with certainty.[92] Doxycycline crosses the blood-brain barrier more effectively than generic tetracycline, and it has been used in combination with other drugs (e.g., rifampin, TMP/SMX) for neurobrucellosis.[78,86] Third-generation cephalosporins achieve high concentrations in CSF, but the sensitivity of brucellae varies and, in general, β-lactam drugs are not effective when used alone.[69] On occasion, patients with *Brucella* endocarditis have been treated successfully with the usual antibiotic

combination; however, most cases have required additional valve replacement surgery.[9]

RELAPSE AND CHRONIC BRUCELLOSIS

The vast majority of patients with brucellosis recover completely within a few weeks to months after receiving adequate therapy. Despite appropriate treatment, some patients suffer a relapse characterized by recurrence of symptoms and re-isolation of brucellae from their blood.[15] Obviously, relapse is more frequent if the full course of treatment is not completed, and taking oral antibiotics for 6 weeks can tax a patient's compliance. With few exceptions, relapse is *not* caused by antibiotic-resistant strains of *Brucella*.[13]

Even with appropriate treatment, some patients will experience a delayed recovery and will continue to have nonspecific complaints, notably fatigue. Such patients have no objective evidence of infection, such as fever, and their antibody titers will decline as expected. Whether this represents a variant of the chronic fatigue syndrome is not clear, but additional antibiotic therapy does not improve their recovery.[33] Rarely, chronic brucellosis occurs from a persisting focus of infection such as osteomyelitis or a deep tissue abscess. Such patients will have fever or other objective signs of infection, and levels of IgG antibodies in the serum remain elevated. Scanning techniques (e.g., scintigraphy with technetium-99m or gallium-67, computed tomography, or magnetic resonance imaging) can be useful in localizing an occult focus of infection.

CHAPTER 129

Pertussis and Other *Bordetella* Infections

James D. Cherry • Ulrich Heininger

Pertussis (whooping cough) is an acute infectious illness of the respiratory tract caused by *Bordetella pertussis* and, less frequently, by *Bordetella parapertussis* and *Bordetella holmesii*.* The illness occurs worldwide and affects all age-groups, but it is recognized primarily in children; it is most serious in young, unprotected infants.[122,226,333,373]

HISTORY

Unlike other severe epidemic infectious diseases of children (e.g., smallpox, poliomyelitis, and measles), pertussis lacks an ancient history.[243] The first observation of pertussis occurred in France in 1414, and the first epidemic was noted in Paris in 1578.[96,112,288] This epidemic and the clinical characteristics of the cases were described in 1640 by Guillaume de Baillou.

Pertussis was noted as *the kink* (a Scottish term synonymous with "fit" or "paroxysm") and *kindhoest* (a Teutonic word meaning "child's cough") in the Middle Ages.[86,243] In 1669, Sydenham named the illness *pertussis* (meaning "violent cough").[288] Isolation of *B. pertussis*, the main causative agent of pertussis, was reported by Bordet and Gengou in 1906.[42,43]

Vaccines consisting of killed whole *B. pertussis* organisms were developed shortly after the bacterium was isolated, and the first results of protection were reported by Madsen in 1925.[319] The mouse protection test, developed and reported by Kendrick and collaborators[274] in 1947, allowed vaccine production to be standardized. Comprehensive studies conducted by the British Medical Research Council[341] in the 1940s and 1950s demonstrated a correlation between the potency of pertussis vaccines as determined by the mouse protection test and their clinical efficacy in children. As a consequence, immunization against pertussis, most commonly in combination with diphtheria and tetanus toxoids (DTP), became part of routine vaccination programs in many countries throughout the world.

Concern about a relationship between pertussis vaccination and temporally associated serious adverse events (e.g., sudden infant death syndrome [SIDS] and a variety of neurologic illnesses) led to a sharp decline in vaccination rates in Japan and several European countries during the 1970s.[77,83,96,279] This concern, along with well-documented high rates of unpleasant local (e.g., swelling and induration) and systemic (mainly fever) reactions, led to the development of new acellular vaccines. These vaccines cause reactions less frequently and have been used in Japan since 1981 and in many developed countries since the mid 1990s.[63,146,220,279,515]

B. bronchiseptica, which causes illness with a cough in a number of animals as well as humans, was first isolated sometime around 1910 by Ferry,[159] McGowan, and perhaps others who were studying dogs with distemper.[333,337] *B. parapertussis* was isolated first from children with pertussis in the 1930s, and *Bordetella holmesii* was noted in nasopharyngeal specimens from patients with pertussis-like illnesses in Massachusetts from 1995 through 1998.[45,148,149,334,545]

MICROBIOLOGY

The genus *Bordetella* contains nine species: *B. pertussis*, *B. parapertussis*$_{hu}$ (adapted to humans), *B. parapertussis*$_{ov}$ (ovine-adapted *B. parapertussis*), *B. bronchiseptica*, *Bordetella avium*, *Bordetella hinzii*, *B. holmesii*, *Bordetella trematum*, and *Bordetella petrii*.[118,193,231,275,333] *B. pertussis* infects exclusively humans. *B. parapertussis* also is a human pathogen, but it has been recovered from sheep ("ovine") as well.[407] Both *B. pertussis* and *B. parapertussis* are respiratory pathogens. *B. bronchiseptica* primarily is an animal pathogen that causes atrophic rhinitis and pneumonia in pigs, kennel cough in dogs, pneumonia in cats, and respiratory illnesses in other animals.[118,182,478] This organism also is the occasional cause of respiratory illness in humans.* *B. avium* is an important cause of respiratory illness in turkeys and other birds.[276]

In addition to *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica*, four other species have been recognized to infect/colonize humans.† *B. holmesii* and *B. hinzii* have been isolated from blood cultures, primarily in patients with underlying chronic illness. *B. holmesii* also has been isolated from the human respiratory tract as has *B. hinzii* and *B. petrii* in patients with cystic fibrosis, and *B. trematum* has been found in wounds and ear infections. *B. petrii*

has been isolated from the environment and is capable of anaerobic growth.[509]

The genus *Bordetella* consists of gram-negative, pleomorphic, aerobic bacilli that are grouped together on the basis of genotypic characteristics, and species are differentiated by phenotypic characteristics. Selected differential characteristics of the four *Bordetella* spp. that cause respiratory illnesses in humans are presented in Table 129-1. All species have relatively simple requirements, but *B. pertussis* is quite fastidious and is inhibited by constituents in common laboratory media such as fatty acids, metal ions, sulfides, and peroxides.[502,535] For laboratory growth, *B. pertussis* requires the addition of "protective substances" such as charcoal, blood, or starch, whereas the other species are less fastidious and may grow in blood or MacConkey agars.

The genomes of representative strains of *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* have been sequenced.[60,409] The genome sizes are as follows: *B. pertussis*, 4,086,186 base-pairs (bp); *B. parapertussis*, 4,773,551 bp; and *B. bronchiseptica*, 5,338,400 bp. *B. pertussis* has 3816 predicted genes, whereas *B. parapertussis* and *B. bronchiseptica* have 4,404 and 5,007 predicted genes, respectively. Pseudogenes occur most commonly in *B. pertussis* (358) and *B. parapertussis* (220) and are uncommon in *B. bronchiseptica* (18). *B. pertussis* has three insertion sequence (IS) elements: IS 481 (238 copies), IS 1002 (6 copies), and IS 1663 (17 copies). *B. parapertussis* has IS 1001 (22 copies) and IS 1002 (90 copies). The sequenced RB50 *B. bronchiseptica* strain contained no IS elements, but studies of other *B. bronchiseptica* strains found strains with IS 481, IS 1001, and IS 1663.[137,169,312,417,486]

Etiology of Pertussis (Whooping Cough)

B. pertussis and *B. parapertussis* are the usual etiologic agents of pertussis, but 86 to 95 percent of illnesses are caused by *B. pertussis*.[105,183,231,411] In rare instances, *B. bronchiseptica*, which normally is enzootic in pigs, dogs, cats, rodents, and other animals, has been isolated from humans with pertussis-like illnesses with a cough.* From 1995 to 1998, *B. holmesii* was isolated from the nasopharynx of 33 individuals in Massachusetts suspected of having pertussis, most of them adolescents and young adults.[334] In contrast to all other *Bordetella* spp., this organism is susceptible to cephalexin, an antibiotic that frequently is added to *Bordetella* culture media.[388] This addition may explain why the organism has not been noted in patients with pertussis in other culture-based laboratory studies.

Adenoviruses have been isolated from children with pertussis, and some researchers have suggested that several adenoviral types on occasion may cause a pertussis-like illness.[22,111,113,379] However, the data of Nelson and associates[379] and Baraff and coworkers,[22] as well as our own observations, lead us to suggest that mixed infections are occurring and that the classic symptoms are caused by *B. pertussis* and not infection with an adenovirus. Wirsing von König and associates noted pertussis-like illnesses caused by viral or *Mycoplasma pneumoniae* infections in 83 patients in whom pertussis laboratory studies were performed and were negative. These authors serologically identified 33 adenoviral illnesses, 18 illnesses caused by parainfluenza viruses, 15 illnesses caused by *M. pneumoniae*, and 14 caused by respiratory syncytial virus (RSV). Wang and colleagues[512] retrospectively studied prolonged illness with cough in 179 children and found that 37 percent had evidence of *B. pertussis* infection and 13 percent had *M. pneumoniae* infections. The cough duration in those with *M. pneumoniae* was of significantly shorter duration (median 39 days) than in children with *B. pertussis* infections (median 118 days). In young infants, coinfection with an adenovirus and perhaps RSV may lead to more severe disease.[30,296] Zouari and associates[550] noted *B. pertussis* and *M. pneumoniae* coinfections in three fatal cases in young infants. Infection with human bocavirus also may cause an illness with a paroxysmal cough.[15] Of 54 children with laboratory-confirmed bocavirus infections, 85 percent had cough and 19 percent had paroxysmal coughing episodes.

Physicians often suggest that *Chlamydia trachomatis* can cause a pertussis-like illness. However, in our opinion, the repetitive cough of *C. trachomatis* is distinctly different from the paroxysmal cough of *B. pertussis* infection, and thus illnesses caused by the two agents usually should not be confused clinically. Infections with *Chlamydia pneumoniae* and *M. pneumoniae* also cause long-lasting illness with cough.[125,204,536] Although infection with these agents in older children and adults can be confused with

*References 44, 107, 133, 195, 383, 462, 478, 479, 541.

TABLE 129-2 **Biologically Active and Antigenic Components of *Bordetella pertussis***

Component	Characteristic
Surface Proteins and Autotransporters	
Fimbriae (FIM)	Two serologic types (types 2 and 3); antibody to specific types causes agglutination of the organism; organisms may contain fimbriae 2, fimbriae 3, fimbriae 2 and 3, or neither fimbriae 2 nor fimbriae 3.
Filamentous hemagglutinin (FHA)	220-kDa surface-associated and secreted protein; highly immunogenic
Pertactin (PRN)	A 69-kDa outer-membrane protein that allows the organism to resist neutrophil-mediated clearance; antibody to pertactin causes agglutination of the organism.
Vag8	95-kDa outer-membrane protein
BrkA	73-kDa surface-associated N-terminal passenger domain with 30-kDa outer-membrane C-terminal protein; confers serum resistance and protection against antimicrobial peptides in *B. pertussis*
SphB1	Subtilisin-like Ser protease/lipoprotein required for FHA maturation
Tracheal colonization factor (TcfA)	60-kDa secreted protein
Toxins	
Pertussis toxin (PT; also called lymphocytosis-promoting factor)	A classic bacterial toxin with an enzymatically active A subunit and a B oligomer-binding protein; effects in an animal model system include histamine sensitization, promotion of lymphocytosis, stimulation of insulin secretion, and adjuvant and mitogenic activity; it is an envelope protein that is also an important adhesin; it adversely affects host immune cell function
Adenylate cyclase toxin (ACT)	Calmodulin-activated RTX family toxin with dual adenylate cyclase/hemolysin activity; acts as an antiphagocytic factor during infection
Dermonecrotic toxin (DNT)	160-kDa heat-labile secreted toxin; induces necrosis in vitro
Tracheal cytotoxin	Disaccharide-tetrapeptide monomeric byproduct of peptidoglycan synthesis; causes mitochondrial bloating, disruption of tight junctions, damage to cilia, and interleukin-1α and nitric oxide production in hamster tracheal and tissue cultures
Type III secretion system	Allows *Bordetella* to translocate effector proteins directly into host cells
Lipopolysaccharide (LPS) (endotoxin)	An envelope toxin with activities similar to endotoxins of other gram-negative bacteria; a significant cause of reactions to whole-cell pertussis vaccines; antibody to LPS causes agglutination of the organism.

B. pertussis infection, true paroxysms typical of pertussis rarely occur.

Antigenic and Biologically Active Components of *Bordetella pertussis*

B. pertussis contains a variety of components that are antigenic or biologically active (Table 129-2).* With the exception of tracheal cytotoxin (TCT), all known virulence factors produced by *B. pertussis* are regulated by the single genetic locus *bvgAS*.[118] Under certain conditions, such as an environmental temperature of 37° C, *bvgAS* is active, toxins and biologically active surface proteins are produced, and the organism is virulent in a mouse model (*bvg*$^+$ phase). In the *bvg*$^-$ phase, a different set of genes (*vrg*, *vir* repressed genes) are expressed, and *B. pertussis* is avirulent in mice in this phase.[520] The switch from *bvg*$^+$ to *bvg*$^-$ is a phenomenon common to all *Bordetella* spp. and is associated with a change in phenotype. An intermediate phase with reduced virulence and expression of specific proteins also has been characterized. Although still speculative, the intermediate phase may have some function in transmission of the organism.[118,468]

*References 1, 10, 11, 13, 24, 54, 80, 96, 118, 119, 157, 180, 213, 217, 220, 233, 236, 238-240, 257, 275, 309, 310, 316, 321, 326, 327, 331, 333, 351, 360, 380, 395, 440, 452, 492, 495, 505, 511, 521, 529, 549.

Fimbriae

Fimbriae are protein projections on the surface of *B. pertussis*.* They are highly immunogenic, and antibody to them, as well as to other antigens, causes agglutination of the organism. Two fimbrial antigens (FIM 2 and 3) are the main agglutinogens; endotoxin and pertactin (PRN) also are agglutinogens.[80,426]

In the past, typing of *B. pertussis* strains was based on the agglutination patterns noted with specific antisera.[80,147,411,426] Six specific agglutinogens were recognized, and typing was based on the presence or absence of agglutination by each specific antiserum. More recently, researchers recognized that two of the agglutinogens (agglutinogens 2 and 3) are fimbrial in location (FIM 2 and 3) and that agglutinogens 4, 5, and 6 are minor antigens.[411,426] All *B. pertussis* strains contain agglutinogen 1. The nature of this agglutinogen is not known.[426] It could be lipopolysaccharide (LPS) or PRN, but because the original serotyping scheme was based on heat-labile antigens, it probably was not LPS.[46,297,484]

The fimbriae function as adhesins, but some studies suggest that in infection they are not the primary adhesins but serve to sustain the attachment established by other attachment factors.[96,427,492,521] An in vitro study by Rodriguez and associates[428] suggested that the effect of

*References 333, 357, 362, 411, 426, 427.

fimbriae on attachment was the result of bacterial agglutination. In the mouse model system, immunization with purified fimbriae resulted in protection against infection when challenged with *B. pertussis*.[269] Data from two trials in which serologic correlates of immunity were studied indicated that antibody to fimbriae is important in protection.[97,472]

Filamentous Hemagglutinin

Filamentous hemagglutinin (FHA) is a component of the cell wall of all *Bordetella* spp.* It is highly immunogenic and is the dominant attachment factor for *Bordetella* in animal model systems.[333,440,451] However, because FHA is released in large amounts from the cell surface, its role as an adhesin must be questioned. Adhesins typically remain associated with the bacterial surface to promote maximum attachment. FHA is a component of most acellular component (DTaP and Tdap) vaccines.[145] However, the importance of antibody to FHA and protection from disease is not clear. Some data indicate that a vaccine containing both pertussis toxin (PT) and FHA had an efficacy greater than that of a vaccine containing only toxoided PT.[470] However, in two studies in which serologic correlates of immunity were evaluated, researchers found that FHA made no contribution to protection.[97,472] Finally, one whole-cell component DTP vaccine in which vaccinees did not mount an antibody response to FHA was, nonetheless, highly efficacious.[224,463]

Pertactin

PRN is a 69-kDa outer-membrane protein that plays an important role in *B. pertussis* pathogenesis by allowing the organism to resist neutrophil-mediated clearance.[37,257,294,388,389] Antibody to PRN has a strong protective effect in aerosol-challenge studies in mice.[76,452] In the two vaccine efficacy trials in which serologic correlates of immunity were evaluated, researchers found that antibody to PRN was most important in protection.[97,472] In addition, the vaccine efficacy trials conducted in the 1990s, in which mild disease and typical disease were evaluated, revealed that DTaP vaccines that contained PRN in addition to PT and FHA clearly were significantly more effective.[84,103,198,333] Another study revealed that anti-PRN antibodies were required for efficient phagocytosis of *B. pertussis* by host immune cells.[234]

Other Autotransporters

In addition to PRN are several other surface-associated proteins (Vag8, BrkA, SphB1, and TcfA) that are considered to belong to the autotransformer family.† All likely play an important active role in *B. pertussis* infection.

Pertussis Toxin

PT is an adenosine diphosphate–ribosylating toxin synthesized and secreted exclusively by *B. pertussis*. It is an A-B toxin with an enzymatically active A subunit (S_1) and a B oligomer ($S_{2\text{-}5}$) binding portion.* PT inactivates G proteins, a process resulting in disruption of signaling pathways and leading to histamine sensitization, enhancement of insulin secretion in response to regulatory signals, and both suppressive and stimulatory immunologic effects in animal model systems.[333] The various effects of PT in animal model systems and in humans were reviewed in depth previously by one of us (J.D.C.).[96,333] In contrast to animal studies, histamine sensitization does not appear to happen in children, but PT does cause an increase in plasma insulin levels.[96,333] PT also is responsible for leukocytosis with lymphocytosis in *B. pertussis* infections. PT is a strong adjuvant in several immunologic systems in animals, but in DTP-vaccinated persons (DTP vaccines contain small amounts of active toxin), only the enhancement of serum antibody responses to antigens of other vaccines has been demonstrated. In mouse and rat models, PT inhibits chemotaxis and migration of neutrophils, monocytes/macrophages, and lymphocytes to infection sites, and PT also functions as an adhesin in the adherence of *B. pertussis* to human macrophages and ciliated respiratory epithelial cells.

In 1979, researchers suggested that pertussis was a single-toxin disease, a suggestion that led to the idea that pertussis could be prevented by a PT vaccine in a manner similar to the success achieved with diphtheria toxoid in diphtheria.[80,404,405] Although convincing arguments to the contrary have been presented, this idea persists.[422,423,489] The most compelling evidence that pertussis from *B. pertussis* infection is not a PT disease is as follows: identical illness results from *B. parapertussis* infection, and this organism does not express PT.[80,231]

However, PT does contribute to morbidity in *B. pertussis* infections, as indicated by the severity of illness, which tends to be greater than that caused by *B. parapertussis* infection. In particular, the frequent finding of extreme leukocytosis caused by PT in neonates and young infants with fatal pertussis is noteworthy.

Adenylate Cyclase Toxin

Adenylate cyclase toxin (ACT) is an extracytoplasmic enzyme that impairs host immune cell function and may contribute to local tissue damage in the respiratory tract.† ACT enters phagocytic cells (particularly polymorphonuclear neutrophils) and, once inside, is activated by calmodulin and catalyzes the production of supraphysiologic amounts of cyclic adenosine monophosphate from adenosine triphosphate, which intoxicates these cells.[333]

Dermonecrotic Toxin

Dermonecrotic toxin (DNT) is a heat-labile toxin described by Bordet and Gengou[43] in 1909. This cytoplasmic protein causes skin necrosis in laboratory animals,[375] and it may contribute to local tissue damage in the respiratory tract.

†References 54, 96, 118, 240, 277, 333, 505, 522.

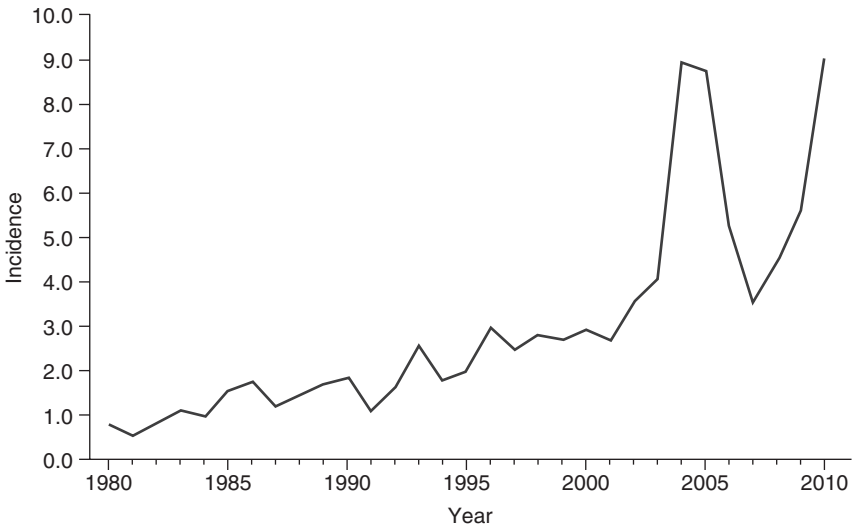

FIGURE 129-1 ■ Pertussis. Incidence per 100,000 population by year—United States, 1980 to 2010. (From Centers for Disease Control and Prevention. Summary of notifiable diseases—United States, 2010. *MMWR Morb Mortal Wkly Rep* 2012;**59**:1–111.)

Tracheal Cytotoxin

TCT is a disaccharide-tetrapeptide monomer of peptidoglycan.[118,180] It causes local damage to respiratory epithelium in hamster tracheal organ cultures and in cultured hamster tracheal epithelial cells and may affect host neutrophil function adversely.[123,180] The cytopathology caused by TCT probably is the result of increases in nitric oxide.[118] It should be noted, however, that the ciliated epithelial cells of infants dying with *B. pertussis* pneumonia were quite well preserved.[399]

Type III Secretion System

The type III secretion system (TTSS) allows *Bordetella* to translocate effector proteins directly into the plasma membrane or cytoplasm of host cells.[157,307]

Lipopolysaccharide (Endotoxin)

The LPS of *B. pertussis* is similar to the endotoxins of other gram-negative bacteria.[74,96,118] Its function in disease is unknown, but it may act as an adhesin.[133] LPS is a major cause of reactions to whole-cell pertussis vaccines.[19] LPS is a significant agglutinogen. Antibody to LPS reduces colonization of *B. pertussis* in the lungs and trachea of mice after aerosol challenge.[370]

EPIDEMIOLOGY

Pertussis is an extremely infectious disease with an estimated R_0 of 12 to 17 (R_0 is the expected number of secondary cases produced by a typical primary case in an entirely susceptible population).[8,99,161]

Today, considerable misinformation is circulating with regard to the epidemiology of pertussis.* The main reason for misinformation is the failure to recognize the significant differences in the dynamics of reported pertussis compared with the dynamics of *B. pertussis* infections.[87,89] The two different epidemiologies are the (1) epidemiology of reported clinical pertussis and (2) the epidemiology of *B. pertussis* infection.

*References 48, 49, 293, 429, 430, 518.

Observed (Reported Pertussis)

Rates of reported pertussis depend on surveillance programs in the reporting countries, states, or counties.[480] For example, in Switzerland and three bordering countries (Germany, Italy, and Austria), the rates of reported pertussis for the period 1998 to 2002 varied by as much as 70-fold.[57] Because the immunization practices in the four countries were somewhat similar and because there is close proximity of the countries, the differences in the rates are explained by the rigorousness of the respective surveillance programs and not unique epidemiology by country.

Incidence

The incidence of reported pertussis and its mortality are affected markedly by the use of pertussis vaccine. In the prevaccine era in the United States, the average attack rate of reported pertussis was 157 per 100,000 population, versus 230 per 100,000 population in England and Wales.[77] Previous studies, however, suggested that reported cases represent only between 15 and 25 percent of cases that actually occur.[216,264,267,469]

With the introduction and widespread use of pertussis vaccines, the attack rate of reported pertussis in the United States fell approximately 150-fold from 1943 to 1976. For the 7-year period from 1976 to 1982, the attack rate in the United States remained between 0.5 and 1.0 per 100,000 population. From 1982 to 2010, the attack rate curve shifted modestly upward and reached a rate of 9.0 per 100,000 in 2010[73] (Fig. 129-1). Possible reasons for the resurgence of reported pertussis that have been suggested are (1) increased vaccine failures resulting from genetic changes in *B. pertussis*, (2) increased vaccine failures related to vaccines of lessened potency, (3) waning immunity, (4) greater awareness of pertussis, and (5) the

availability of better laboratory tests.* Of these possibilities, it is our opinion that greater awareness was initially the most important. Also of importance is the use of polymerase chain reaction (PCR) for diagnosis and that, in general, DTaP vaccines are less efficacious than are DTP vaccines, which, in particular, may be a contributing factor relating to the increase in reported pertussis in older children and adolescents. The number of cases and the attack rate in adolescents and adults will increase further when single serum serologic diagnosis becomes routine.[106] Finally, the data from California indicate that waning immunity is a major factor. In looking at Figure 129-1, there appears to be two periods. In the first period, the increase in cases is mainly due to increased awareness. In contrast, the sharp peaks in 2004 to 2005 and in 2010 are most likely due to DTaP vaccine failure, waning immunity, and PCR diagnosis.

In recent years, there has been considerable debate regarding the role of genetic change in the cause of vaccine failure.[106,130,362,390,446] Over time, it is clear that genetic changes in PT, PRN, and fimbriae have occurred. In fact, Preston[410] in 1965 noted that the British vaccines at the time contained only agglutinogen 2 (FIM 2) and that circulating *B. pertussis* strains contained agglutinogen 3 (FIM 3). However, we believe at the present time that genetic change has not contributed to vaccine failures. If genetic change were to lead to vaccine failure, one would expect it to occur first in Denmark where physicians have been using a single-component PT toxoid vaccine for 15 years.[92] At present, there are no data suggesting increased vaccine failure in Denmark.

Pertussis epidemics in the prevaccine era occurred at 2- to 5-year intervals (average, 3.2 years), and these cycles have continued in the vaccine era. As noted by Fine and Clarkson,[160,163] this continuation of the same cycles today as occurred in the prevaccine era indicates that, although immunization has controlled disease, it has not reduced transmission of the organism in the population.[77,82,85]

In the prevaccine era, the following percentages of cases by age were noted in Massachusetts: younger than 1 year, 7.5 percent; 1 to 4 years, 41.1 percent; 5 to 9 years, 46.0 percent; 10 to 14 years, 4.1 percent; and 15 years and older, 0.9 percent.[42] Associated with the marked reduction in reported cases of pertussis in the United States resulting from widespread pediatric immunization, a major shift occurred in the percentages by age category.[42] During the period from 1978 to 1981, the age distributions were as follows: younger than 1 year, 53.5 percent; 1 to 4 years, 26.5 percent; 5 to 9 years, 8.2 percent; 10 to 14 years, 5.4 percent; and 15 years or older, 6.5 percent. In contrast, U.S. data for 2010 revealed the following: younger than 1 year, 15 percent; 1 to 6 years, 22 percent; 7 to 10 years, 18 percent; 10 to 19 years, 20 percent; and 20 years or older, 25 percent. Today, pertussis in adolescents and adults is an important source of *B. pertussis* infection in unimmunized or partially immunized children.† Disease in adolescents and adults usually is not recognized as pertussis, even though the cough frequently is paroxysmal and the illness may persist for weeks.[85,132,325,408,447]

In a study in university students, members of our group found that 26 percent of students with an illness with cough of 6 days' duration or longer had *Bordetella* infections, none of which had been diagnosed correctly clinically.[356] The findings in this study led to the suggestion that *B. pertussis* infections are endemic in adults and are responsible for cyclic outbreaks in susceptible children. More recent studies in the United States, Germany, and elsewhere support this hypothesis.*

Morbidity and Mortality

During the first 30 years of the 20th century, pertussis was an important cause of death in the United States.[288] The number of deaths from pertussis in the United States between 1926 and 1930 was 36,013,[183] and most of these deaths occurred in children younger than 1 year of age. The pertussis death rate curve in the United States declined throughout the 20th century. In infants, the mortality rate decreased approximately fivefold from 1900 to 1944. During the next 35 years, it declined more than 85-fold.[367,368] Today, most of the deaths caused by pertussis occur in unimmunized infants younger than 6 months of age.† Currently in the United States, 10 to 20 deaths are reported each year.‡

Of importance is that deaths caused by pertussis frequently are misdiagnosed as deaths from other respiratory tract infectious illnesses.[77,228,384] For example, in England and Wales during the epidemic from 1977 to 1979 and at the beginning of the epidemic in 1982, 32 deaths were reported to be caused by pertussis.[77] However, when the excess deaths from other respiratory tract infectious illnesses were examined, approximately 362 additional deaths appeared to be caused by pertussis. Additional pertussis deaths were reported as SIDS.[384]

The morbidity caused by pertussis in recent years can be gleaned from numerous reports. The numbers of pertussis-related hospitalizations, complications, and deaths in the United States during 1990 to 1996 were reviewed in 1999 by Güris and colleagues.[197] Of the 31,837 cases analyzed, 31.7 percent of these patients were hospitalized, 9.5 percent had pneumonia, 1.4 percent had seizures, 0.2 percent had encephalopathy, and 0.2 percent died. The most severe morbidity occurred in infants younger than 6 months of age. Of this group, 72.2 percent were hospitalized, 17.3 percent had pneumonia, 2.1 percent had seizures, 0.5 percent had encephalopathy, and 0.5 percent died. During the period from 2000 to 2004, 12,174 cases in infants were reported.[70] Of this group, 62.8 percent were hospitalized, 55.8 percent had apnea, 12.7 percent had pneumonia, 1.5 percent had seizures, and 0.8 percent died.

In adolescents with reported pertussis, 0 to 2 percent are hospitalized and 2 percent have pneumonia.[69] In a review of data from seven studies of reported adult pertussis, the following findings were noted: hospitalization,

3 to 12 percent; seizures, 0 to 0.6 percent; rib fracture, 0 to 4 percent; and pneumonia, 0.6 to 8 percent.[70]

A pertussis surveillance system was introduced in conjunction with a large pertussis vaccine efficacy trial in several regions of Germany in 1990. The initial results of this ongoing surveillance study were published in 1993.[222] Of 601 culture-proven cases, 12.3 percent occurred in infants and 86.2 percent occurred in children younger than 6 years of age. Serious complications were reported in 22 of 275 patients with follow-up. These complications included pneumonia in 5.5 percent, apnea in 2.2 percent, and cardiorespiratory failure in 0.4 percent.

In a follow-up report of the same study, 1 of 185 culture-confirmed cases in infants was fatal.[226] In another German study from 1993 to 1996, Herzig and associates[178] noted 116 hospitalized pertussis patients with the following complications: pneumonia in 81 percent, apnea requiring assisted ventilation in 15 percent, seizures in 14 percent, encephalopathy in 5 percent, and death in 2 percent. In Canada from 1991 to 1997, Halperin and colleagues[211] analyzed the complications of pertussis in 1082 hospitalized children younger than 2 years of age and noted that 9.4 percent had pneumonia, 3 percent had atelectasis, 2.3 percent had seizures, 0.59 percent had encephalopathy, 0.8 percent had inguinal or umbilical hernias, 1.3 percent had more than a 5 percent weight loss, and 0.9 percent died.

Season, Geography, Race, Ethnicity, and Sex

Pertussis occurs throughout the world.[96] Historically, epidemic pertussis had no seasonal pattern.[77] However, in the present vaccine era in North America, pertussis usually occurs in the summer and fall.* The incidence of pertussis is usually greater in female than in male patients.[77,155,184,197,516] In 2004, 25,827 cases were reported in the United States, and of these patients, 11,199 (45%) were male and 13,879 (55%) were female (sex not identified in 749 cases).[65] In 2010, 55 percent of the reported cases were females. In the large study in Germany, 1,263 (50.7%) of the 2,493 subjects were female.[226]

Reported pertussis rates were higher in American Indians/Alaska Natives and whites than in Asians/Pacific Islanders and blacks in 2010.[73] Attack rates were also higher in Hispanics than in non-Hispanics.

Transmission

Transmission is thought to occur by droplets from a coughing patient that reach the upper respiratory tract of a susceptible person. Indirect spread also possibly occurs. A symptomatic patient could contaminate the environment with respiratory secretions. The hands of the new host-to-be make contact with the secretions and then may inoculate the respiratory tract.[96] Attack rates in susceptible household contacts range from 70 to 100 percent.[77,96] Antibody studies indicate that asymptomatic infections also occur in contacts.[135,313,314] These asymptomatic infections are likely to be short lived and probably are not important with regard to contagion. Transmissibility is greatest early in the illness, that is, during the catarrhal and early paroxysmal phases.

Bordetella pertussis Infection

In general, the cyclic pattern of reported pertussis is similar today to what it was in the prevaccine era.[333] This pattern is still different from that seen with other diseases that have been brought under control by universal immunization.[85,87,89,356] An example is measles. As this disease was brought under control, the interepidemic cycle lengthened because circulation of the measles virus in the population had been reduced. In contrast, with pertussis, immunization controlled disease but did not decrease the circulation of *B. pertussis*.[163,164] In the 1970s, Nelson[378] noted that the source of *B. pertussis* infection in hospitalized infants most often was an adult. This observation led many investigators to suspect that *B. pertussis* infections were endemic in adolescents and adults.[85,356] Sporadic infection in the adolescent and adult reservoir is the major source of *B. pertussis* infections in nonimmune children. The cyclic pattern occurs because it takes a few years for a significant number of susceptible members of the population to develop so that an outbreak will result from the sustained transmission.

Our present understanding of the importance of adolescent and adult *B. pertussis* infections has been the result of the ability to diagnose infection serologically by measuring immunoglobulin (Ig) G and IgA antibodies to PT by enzyme-linked immunosorbent assay (ELISA)*. During the past 25 years, numerous studies in adolescent and adult populations have contributed to our understanding of *B. pertussis* epidemiology.

Studies of prolonged illnesses with cough in adolescents and adults suggest that between 13 and 20 percent of the illnesses are caused by *B. pertussis* infection.† Many studies have looked at overall infection rates by determining significant IgG or IgA titer rises to PT in persons who have two or more serum samples collected over extended periods.‡ These studies suggest that between 1.0 and 6.7 percent of adolescents and adults have a *B. pertussis* infection each year. In another large study in the Netherlands, which used a combination of serologic surveys, an incidence of infection of 6.6 percent per year for persons between the ages of 3 and 79 years was estimated.[131] The incidence in children 3 to 4 years of age was 3.3 percent. It then increased gradually to a peak of 10.8 percent in those 20 to 24 years of age. Other age-specific incidences were 6.5 percent in persons 25 to 55 years old and 4.0 percent in those older than 55 years of age.

The specific rates of illnesses with cough caused by *B. pertussis* were determined in two prospective specific population-based studies.[475,513] In the first study the rate was 500 per 100,000 (0.5%), and in the second it was

*References 87, 89, 106, 333, 356, 413

†References 38, 87, 89, 178, 265, 333, 356, 381, 433, 447, 475, 507, 534, 544.

‡References 87, 89, 120, 136, 241, 333, 514.

370 per 100,000 (0.37%). In addition, the retrospective serologic analysis of a respiratory disease study in adults older than 65 years suggested a rate as high as 1.5 percent.[241] This high value assumes that all respiratory illnesses with cough during the 4-month periods of seroconversion were the result of *B. pertussis* infection.

With increased clinical surveillance and more complete use of the laboratory (PCR and serologic study) and the diagnosis of mild cases in children, adolescents, and adults of all ages, the present cyclic pattern of reported pertussis will, for the most part, disappear. In fact, the pattern of reported pertussis has already lost some of its predictable regularity in some European countries with rigorous surveillance systems in place.

PATHOLOGY

Data on pathology of *B. pertussis* infections have been determined mainly by postmortem study in fatal cases.* However, information relating to uncomplicated pertussis can be gleaned from experiments using rhesus and ringtail monkeys.[288,442] In these studies, pure cultures of *B. pertussis* have been obtained from between the cilia of the smaller bronchi and bronchioli. Endobronchitis and peribronchitis are noted, and the bronchi contain leukocytes, mucus, and debris.

In a recent study of autopsy material from 15 infants (≤4 months old), the consistent histopathologic features were necrotizing bronchiolitis and pneumonia, intra-alveolar hemorrhage and fibrinous edema, and abundant intra-alveolar macrophages.[399] Angiolymphatic aggregates of mixed leukocytes in the intralobular septa and pleurae were seen in 86 percent of the specimens. Intact *Bordetella* were noted in cilia of the trachea, bronchi, and bronchioles and within airways and alveoli. They also were noted intracellularly in alveolar macrophages and respiratory epithelium. Despite the fact that all patients had severe pneumonia, the ciliated respiratory epithelial cells appeared relatively normal. Six of the respiratory specimens had evidence of coinfections with one or more other agents (cytomegalovirus, 1 child; RSV, 2 children; *Streptococcus pneumoniae*, 2 children; *Streptococcus pyogenes*, 2 patients; *Moraxella catarrhalis*, 1 child; and viridans streptococci, 1 child).

Pathologic changes in the brain and liver also have been described. Microscopic or gross cerebral hemorrhage may be noted, and cortical atrophy has been observed. These changes most likely are the result of anoxic brain damage. In some studies of pertussis encephalopathy, findings suggested meningoencephalitis, with perivascular cuffs of lymphocytes within cerebral gray matter and pleocytosis.[540] However, the studies in which inflammation was demonstrated were performed before modern virologic techniques became available. Probably, the neurologic findings in these instances were caused by interactions with neurotropic viruses or other infectious agents and were not the result of *B. pertussis* infection.[96] Fatty infiltration of the liver has been noted in patients with pertussis encephalopathy.

PATHOGENESIS AND IMMUNITY

After the patient is exposed to *B. pertussis*, the pathogenesis of infection depends on four important steps: attachment, evasion of host defenses, local damage, and systemic disease.* The biologically active antigenic components of *B. pertussis* listed in Table 129-2 have various roles in pathogenesis. During the past two decades, there have been literally hundreds of research publications exploring the effects of various *B. pertussis* proteins in animal model systems. These studies have revealed a large amount of information, but what is missing for the most part is the correlation or lack of correlation with pathogenesis in human infections.†

Infection is initiated in the respiratory tract by the attachment of *B. pertussis* organisms to the cilia of ciliated epithelial cells.[521] Adhesins (FHA, PT, FIM, LPS) facilitate this attachment.[412] Because of the redundancy of protein adhesins, determining the importance of the individual proteins and ascertaining a primary adhesin or adhesins have been difficult.[333] In animal model systems, FHA is an important adhesin; however, data from two vaccine efficacy trials in which serologic correlates of immunity were studied suggested that FHA may not be necessary if other proteins are present.[97,472] Data from one of these efficacy trials noted that a DTP vaccine that contained a minimal amount of FHA and generated a minimal anti-FHA response had greater efficacy than did a DTaP vaccine that contained a large amount of FHA and generated a vigorous antibody response to FHA.[224,463] However, in a study in which a PT toxoid vaccine was compared with a two-component PT/FHA vaccine, researchers found that the two-component vaccine was more efficacious.[2,470,471,473] This finding suggests that in the absence of antibody to other proteins, antibody to FHA contributes to protection.

Of the other attachment proteins, data relating to human infection are available for fimbriae only. In the two trials that looked at serologic correlates of immunity, researchers found in both that antibody to fimbriae was important.[94,472] Antibodies against fimbriae were shown to provide protection against colonization with *B. pertussis* in the murine respiratory tract.[528]

In many publications, PRN as well as other autotransporters are listed as being adhesins, which, for the most part, is incorrect. The reason for this belief is that antibody to PRN is associated with lack of attachment. However, PRN and other autotransporters have specific biologic activities in infection.‡ The two household contact studies of serologic correlates of protection both found that antibody to PRN was most important in preventing pertussis.[97,472]

Both ACT and PT adversely affect immune cell function and, therefore, allow infection, once initiated, to continue.* PT prevents migration of lymphocytes and macrophages to areas of infection and adversely affects phagocytosis and intracellular killing. ACT enters phagocytic cells and catalyzes excessive production of cyclic adenosine monophosphate, which intoxicates neutrophils and results in a decrease in phagocytosis.

TCT and DNT have been implicated as contributors to local tissue damage in the respiratory tract.[96,180,375] However, there are no data indicating tissue damage in human infections due to these two toxins.

Pertussis is a unique illness in that fever does not occur and it has only one manifestation of systemic disease in uncomplicated infection: leukocytosis with lymphocytosis caused by PT.[96,231,255] T and B lymphocytes increase to a similar extent in the circulation.[35] In contrast to the situation in *B. pertussis* infection, leukocytosis with lymphocytosis is not a characteristic of *B. parapertussis* infection because this organism does not liberate PT. Clinical experience and recent studies indicate that PT is the major causative factor in deaths in young infants.[373,399] PT inhibits G proteins, and this is the cause of the leukocytosis with lymphocytosis. It has been suggested that the extreme leukocytosis results in obstruction in small pulmonary vessels and this leads to severe pulmonary hypertension.[399] However, it is possible that the inhibition of G proteins in other cells in the lung or heart is the cause of death.[373] An important systemic complication of pertussis is encephalopathy, the mechanism for which is not known. The most likely explanation is anoxia associated with coughing paroxysms.

Some investigators have suggested that pertussis is a toxin-mediated disease caused by PT.[404,405] Although some researchers continue to entertain this idea,[422,423] little evidence supports it. Undoubtedly, PT is a fascinating protein with multiple activities in experimental animals, such as histamine sensitization, promotion of lymphocytosis, effects on glucose metabolism, and induction of adjuvant and mitogenic activity.[96,174,333,372] However, in infections in humans, the main effects that appear to be caused by PT are lymphocytosis and mild, compensated hyperinsulinemia. PT has been suggested to be the cause of the prolonged cough in pertussis. However, because persistent cough is a major manifestation of *B. bronchiseptica* infection in dogs and of *B. parapertussis* infection in children, and because neither organism liberates PT, this hypothesis should be refuted.[231,333,389]

The hallmark of *B. pertussis* illness is paroxysmal cough, and the cause is unknown. The paroxysmal cough is unique because of its long duration. In addition, there is memory for the cough so that it may return when people have subsequent respiratory tract viral infections. Recently, Hewitt and Canning[237] have suggested that bradykinin plays a role in the initiation of the cough. During *B. pertussis* infection, bradykinin production is increased and has a prolonged half-life in the airways and responsiveness to bradykinin reception activation is increased. Bradykinin activates sensory nerves implicated in cough. What is not known is the *Bordetella* protein or proteins that stimulate the unique coughing process.

Cell-mediated immune function is altered by *B. pertussis* infection. In some studies, cell-mediated immunity was depressed, whereas in others it was augmented.[396]

Various antibodies develop after exposure of the human host to infection with *B. pertussis*. The development of agglutinins, hemagglutination-inhibiting antibodies, and bactericidal antibodies has been described.[77] ELISA techniques have demonstrated class-specific antibodies (IgA, IgE, IgG, and IgM) to many of the specific proteins of *B. pertussis*.[219,323,397] These antibodies develop after infection and, with the exception of IgA antibodies, also after immunization. Neutralizing antibody to PT likewise develops after both infection and immunization.[207,397] Specific IgA antibodies to PT and FHA also can be demonstrated in nasopharyngeal secretions and saliva.[186,547]

At present, both *B. pertussis* infection and immunization with whole-cell or acellular pertussis vaccines clearly elicit protection of varying degree and duration against pertussis. The prevailing opinion throughout the past century was that immunity acquired from having *B. pertussis* infection is lifelong whereas vaccine-induced immunity is relatively short-lived. Although the latter clearly is true,[163] studies performed by members of our research group suggest that the former opinion regarding infection-induced immunity is wrong.* Proceeding from the knowledge that IgA antibodies to pertussis antigens (PT, FHA, and PRN) result from infection and not from primary vaccination, our group studied the prevalence of these antibodies in the sera of young German and American men of similar ages.[95] In Germany, routine childhood immunization was not carried out during the 1970s and 1980s and pertussis was epidemic. To our surprise, the rate and mean values of IgA antibodies in the two populations were similar, thus suggesting that adult infection rates were similar. In another study in Germany, we found that *Bordetella* infections were common occurrences in adults, often in persons with a known history of childhood pertussis.[447]

The nature of immunity in pertussis is not known. The consensus has been that serum antibodies greater than some unknown concentration to one or more of the pertussis antigens are responsible for protection.[135] Antibodies to PT, FHA, and PRN have been shown to be protective in animal model systems.[37,119,294,440,452] However, no serologic correlates of immunity had been established until relatively recently, although several large vaccine trials were carried out in the late 1980s and early 1990s.† In a nested household contact study, our group was able to evaluate the roles of IgG antibodies to PT, FHA, PRN, and FIM 2 by determining preexposure imputed values in children at the time of household exposure to *B. pertussis* infection by using both classification tree and logistic regression methods.[97] The imputed geometric mean antibody values to PT, PRN, and FIM 2 were higher in noncases than in cases. In the classification tree analysis, however, only antibodies against PRN contributed

*References 10, 11, 54, 96, 240, 372, 505.

*References 83, 86, 95, 333, 447, 504.
†References 2, 188, 198, 300, 454, 463, 490.

significantly to protection. Specifically, subjects with an imputed PRN value of less than 7 endotoxin units (EU)/mL had a 67 percent likelihood of infection. Logistic regression analysis also found that PRN values of 8 EU/mL or more were associated with prevention of illness after household exposure. In accordance with our findings, data from a Swedish study indicate that antibody values of 5 EU/mL or more to PRN and FIM 2/3 correlated with protection.[472] The data from these two studies indicate that antibody to PRN and FIM are most important in protection. However, what is difficult to understand is why some children get pertussis in spite of large amounts of antibody to either or both PRN and FIM.[100,489] Data from a study by Weiss and associates[99,523] suggested that high antibody values to PT may have a blocking effect on the protective effect of antibody to the more important antigens.

In addition to humoral responses to several *B. pertussis* antigens, evidence exists that cell-mediated immune responses to PT, FHA, and PRN also occur.* Studies in a murine respiratory tract infection model suggest that cellular immunity plays an important role in bacterial clearance and augments the effects of antibody by predominantly T-helper 1 (Th1) cell stimulation.[352,353] Studies in humans demonstrate a cellular immune response shortly after natural infection with *B. pertussis*, with PT, FHA, and PRN preferentially inducing the synthesis of Th1 cells.[527] Immunization with a whole-cell pertussis vaccine results in a Th1 response, whereas the response to acellular vaccines is more heterogeneous and involves both Th1 and Th2 cells.[61] Persistent memory T and B cells and anamnestic antibody responses are important in long-term immunity.[320]

Immunity developed after having *B. pertussis* infection or receiving vaccination with a whole-cell pertussis vaccine does not protect against illness caused by *B. parapertussis*, and, similarly, infection with *B. parapertussis* does not induce protection against disease caused by *B. pertussis*.[289,483] However, in our vaccine efficacy trial in Germany, the results showed some evidence that the acellular pertussis multicomponent vaccine, which contained a large amount of FHA, offered some protection against *B. parapertussis* infections, whereas the whole-cell vaccine, which contained minimal amounts of FHA, did not.[229] Although *B. pertussis* infection is a localized infection involving ciliated cells of the respiratory tract, bacteremia has been noted in immunocompromised adults.[68,263,491]

CLINICAL MANIFESTATIONS

The clinical manifestations of *B. pertussis* infection have considerable variation that depends on age, previous immunization or infection, the presence of passively acquired antibody, and perhaps other factors such as the degree of exposure, host genetic and acquired factors, and the genotype of the organism. The incubation period for pertussis generally varies between 6 and 20 days; most cases have an onset 7 to 10 days after exposure. However, after household exposure, 22 percent of secondary cases were noted to have an onset more than 4 weeks after the onset of illness in the primary case.[224]

Classic Illness

Classic illness occurs as a primary infection in unimmunized children between the ages of 1 and 10 years.[86,96,106,183,396] The illness usually lasts 6 to 12 weeks and has three stages: catarrhal, paroxysmal, and convalescent. The initial illness is characterized by rhinorrhea, lacrimation, and mild cough suggesting a common cold. Body temperature usually is normal. The severity of the cough gradually increases over a period of 1 to 2 weeks, but pertussis usually is not suspected until the cough becomes paroxysmal.

After the catarrhal period, the coughs increase in severity and number. Repetitive series of 5 to 10 or more forceful coughs during a single expiration can be noted. These paroxysms are followed by a sudden massive inspiratory effort, and a characteristic whoop may occur as air is forcefully inhaled through a narrowed glottis. Cyanosis, bulging eyes, protrusion of the tongue, salivation, lacrimation, and distention of neck veins occur during paroxysms. Several paroxysmal coughing episodes with their associated massive inspiratory effort may occur sequentially until the child succeeds in dislodging the obstructing mucus. The production of purulent sputum does not occur. Posttussive vomiting is a common occurrence. Paroxysms may strike several times per hour, and they occur during both day and night.

The paroxysmal episodes are exhausting, and patients frequently appear dazed and apathetic. Weight loss may occur as a result of vomiting and also because eating and drinking may be resisted, given that they trigger attacks. Attacks also may be triggered by yawning, sneezing, or physical exertion. Between attacks, the patient may appear normal and usually is in no distress.

Common and important complications of classic pertussis include pneumonia, otitis media, seizures, and encephalopathy. Pneumonia may be caused by *B. pertussis* or secondary bacterial invaders. Atelectasis may develop as a result of the mucus plugs. The forcefulness of the paroxysms can cause rupture of the alveoli and can produce interstitial or subcutaneous emphysema.

Otitis media is a common occurrence and frequently is caused by *S. pneumoniae*. Pertussis also has been associated with activation of latent tuberculosis. Convulsions and coma may be observed. These findings may be a reflection of cerebral hypoxia related to asphyxia. Rarely, subarachnoid and intraventricular hemorrhage may occur. Tetanic seizures may be associated with the severe alkalosis that results from the loss of gastric contents caused by persistent vomiting.

Other complications that have been noted include ulcer of the frenulum of the tongue, epistaxis, melena, subconjunctival hemorrhage, subdural hematoma, spinal epidural hematoma, rupture of the diaphragm, umbilical hernia, inguinal hernia, rectal prolapse, dehydration, meningoencephalitis, the syndrome of inappropriate

*References 17, 320, 352-354, 436,437, 488, 527, 548.

secretion of antidiuretic hormone, apnea, rib fracture, and nutritional disturbances.*

The convalescent stage, which usually lasts 1 to 2 weeks, is characterized by a decreasing frequency and severity of coughing episodes, whooping, and vomiting. All patients with classic pertussis caused by primary infection have leukocytosis associated with lymphocytosis. Fever and pharyngitis are not usual manifestations in pertussis, and, therefore, a search for a secondary cause should be undertaken when these findings occur. Except for the observation of typical paroxysms, physical examination in pertussis usually is unrewarding. Diffuse rhonchi may be noted on auscultation.

Infection with *B. parapertussis* causes an illness that is similar to that caused by *B. pertussis*, but generally it is less severe and of shortened duration.[230,301,330]

Mild Illness and Asymptomatic Infection

Mild, nonclassic illness is common in *B. pertussis* infection.[135,222,226,444] It occurs in previously vaccinated individuals and also as a primary infection in nonvaccinated children. In a study in which physicians were encouraged to send nasopharyngeal specimens from ill children with cough, regardless of whether the illness was typical of pertussis, to our laboratory,[222] 247 culture-positive cases were noted. Of these patients, 47 percent had a total duration of cough of 28 days or less. In 26 percent, the duration of cough was less than 3 weeks. Most of these cases occurred in unvaccinated children. In a 6-year, similar study involving 2592 culture-positive, previously unvaccinated children, 38 percent had a duration of cough of 28 days or less and in 17 percent it was 21 days or less.[226] In a study in which both culture and PCR were used for establishing the diagnosis of *B. pertussis* infection, many mild cases were found to be PCR positive and culture negative.[444] Of the patients with these cases, only 68 percent had a cough lasting 4 weeks or longer and only 57 percent and 32 percent had paroxysmal cough and whoop, respectively.

In studies of household contacts, asymptomatic infections in family members are common occurrences.[135,313,314] Deen and associates[135] found that 52 (46%) of 114 household contacts who remained well had laboratory evidence of *B. pertussis* infection. In another study, 21 of 399 healthy infants who were control subjects had PCR-positive nasopharyngeal samples.[225]

Infants

Pertussis in infancy is a unique experience.[333] Its spectrum of clinical manifestations varies by age, immunization, and the presence or absence of transplacentally acquired antibody.† Most deaths resulting from *B. pertussis* infection occur in neonates and early infancy, and morbidity is most severe in infants.‡ From 1997 through 2000, 8276 cases of pertussis were reported in infants in the United States.[64] Of this group, 59 percent of the infants were hospitalized, 11 percent had pneumonia, 1 percent had seizures, 0.2 percent had encephalopathy, and 0.7 percent died. Eighty-seven percent of these cases occurred in children younger than 6 months of age.

B. pertussis infection in neonates is particularly severe, with a death rate of between 1 and 3 percent.* Clinical characteristics of pertussis in early infancy are presented in Table 129-3. A common initial finding is apnea, and typical coughing may not be observed. Seizures in association with apnea caused by hypoxia occur frequently. Severe pulmonary hypertension is a relatively common problem in pertussis in the first 4 months of life.† The severity of disease and the risk for death correlate directly with the white blood cell (WBC) count and, in particular, the number of lymphocytes.‡ WBC counts in the range of 30,000 to more than 100,000 cells/mm^3 are common findings. A recent California Department of Public Health study provided useful information relating to risk factors for pulmonary hypertension and death.[373] This first study involved 31 infants 90 days of age or younger with pertussis admitted to a pediatric intensive care unit in Southern California. Infants with pulmonary hypertension or who died had higher WBC counts, had more rapid pulse and respiratory rates, and were more likely to have pneumonia than those who did not have pulmonary hypertension or died. In addition, in those with pulmonary hypertension or who died, the WBC count rose more rapidly and the pulse and respiratory rates attained higher levels sooner than in those without pulmonary hypertension or who died.

Coinfection with respiratory viruses (RSV, adenovirus, influenza viruses) and respiratory bacterial pathogens

TABLE 129-3 **Clinical Features of Pertussis in Young Infants**

Initially infant looks deceptively well; coryza, sneezing, clearing throat, no fever, mild cough
Paroxysmal stage: gagging, gasping, eye bulging, bradycardia (tachycardia occurs in severe illness), cyanosis, vomiting
Leukocytosis with lymphocytosis
Apneic episodes
Seizures
Respiratory distress
Pneumonia and pulmonary hypertension
Shock/hypotension with renal failure
Death associated with pulmonary hypertension and pneumonia
Adenovirus or respiratory syncytial virus coinfection can confuse picture

(Streptococcus pneumoniae, Haemophilus influenzae) are relatively frequent.*

B. pertussis infection has been noted in association with SIDS, but whether a cause-and-effect relationship exists is not clear.[225,230,303,384] Nichol and Gardner,[384] in a study in England, found that many deaths attributed to SIDS were, in fact, related to *B. pertussis* infection. Using PCR, we found *B. pertussis* DNA in nasopharyngeal specimens from 9 (18%) of 51 infants who had sudden, unexpected deaths.[230] In a subsequent study, we collected specimens for PCR from 254 infants who experienced sudden, unexplained deaths and from 441 healthy matched controls.[225] The rate of PCR-positive results in the sudden death cases was 5.1 percent; it was 5.3 percent in the controls. In a careful follow-up histopathologic study with unique immunohistochemical staining of specimens from a subset of these fatal cases, we could find no evidence of specific *B. pertussis* pulmonary infection or pathologic features.[104]

The source of infection in infants usually is a family member.† In a study of 616 infant cases, the source was identified in 43 percent.[39] A family member was the source 75 percent of the time, and the mother was the most common source (32%). Of the source persons, 56 percent were adults and 20 percent were 10 to 19 years of age.

Adults

Increased awareness of adult pertussis has occurred since the 1970s.‡ Unrecognized pertussis cases in adults often are the source from which infants and children become infected.§ All adults previously have been exposed to *B. pertussis* antigens by immunization, infection, or both,[95,135,136,333] and this exposure tends to modify their illness. In a U.S. study, the following cough characteristics were noted in 31 university students with laboratory evidence of *Bordetella* infection: the median duration was 21 days before initial evaluation, 94 percent had one or more coughing episodes per hour, and 90 percent of the coughs had a staccato or paroxysmal quality.[356] Despite these findings, pertussis was not suspected in any of the students; and clinical diagnoses by the primary care providers included upper respiratory tract infection (39%), bronchitis (48%), and other diagnoses (16%). Although specific records were not available, most of these students probably were vaccinated as children and almost certainly had previous, unrecognized infections.[95,135]

In contrast to these findings in the United States, in a study in Germany adults were found to be more likely to have typical pertussis, even though the epidemiologic data suggested that all had a previous infection and 26 percent of 64 patients with laboratory evidence of infection recalled having had pertussis during childhood.[95,447] Rates of clinical manifestations in the 64 laboratory-confirmed cases were as follows: paroxysms, 70 percent; whoop, 38 percent; post-tussive phlegm, 66 percent; and posttussive vomiting, 17 percent. The clinical diagnosis in 39 percent was definite or probable pertussis; only 14 percent were thought not to have pertussis. Of note is that the clinical diagnosis was not made by primary care physicians but by a small team of specially trained central investigators with high awareness for pertussis.

Similar findings were noted in a German household contact study: 80 percent of 79 adults with laboratory-confirmed *B. pertussis* infection coughed for 3 or more weeks and 63 percent had spasmodic cough for 3 or more weeks.[408] In addition, in 53 percent of patients, coughing was followed by choking or vomiting. However, only 8 percent of the adults in this study had whoops. Complications that were observed included pneumonia, rib fracture, inguinal hernia, and severe weight loss. Unique sweating episodes are reported in approximately 5 percent of adults, and fainting can occur in association with coughing.[132,408]

DIFFERENTIAL DIAGNOSIS

In typical pertussis, the clinical diagnosis should be apparent based on the paroxysmal cough with posttussive vomiting and whooping and lack of significant fever. However, the cause of the illness can be *B. pertussis*, *B. parapertussis*, *B. holmesii*, and perhaps *B. bronchiseptica*. A history of contact with a known case will help to establish the diagnosis in a patient with mild or atypical illness. The presence of leukocytosis with lymphocytosis in a child with a cough or the presence of apnea in an infant is a strong indication that the illness is caused by *B. pertussis* and not another *Bordetella* spp. In a matched-control comparison, none of 11 children with culture-proven *B. parapertussis* infection versus 7 of 22 (32%) with *B. pertussis* infection had lymphocytosis of 10,000 cells/mm^3 or more.[231] Lymphocytosis of 10,000 cells/mm^3 or more is observed in few other illnesses that manifest with a cough.

Many other infectious agents cause illnesses with prolonged and repetitive cough that can be confused with *B. pertussis* infections.[333] In particular, *M. pneumoniae*, *C. pneumoniae*, adenoviruses, bocavirus, and other respiratory viruses all can cause a prolonged cough.* In addition, coughing episodes may be seen in children with asthma, bronchiolitis, bacterial pneumonia, cystic fibrosis, *Coccidioides immitis* infection, and other fungal pulmonary infections and tuberculosis. Another problem is the cough associated with sinusitis, which can be confused with *B. pertussis* infection. The cough associated with gastroesophageal reflux also can be confused with pertussis, as can cough associated with a foreign body in the airway.

DIAGNOSIS

A laboratory diagnosis of pertussis caused by *B. pertussis* or other *Bordetella* spp. can be made by culturing the

organisms on appropriate media, by PCR, and by demonstrating the presence of specific antibodies. *Bordetella* spp. can be recovered from nasopharyngeal specimens, with the highest rate of isolation occurring within the first 3 weeks of cough.[222,474] Specimens for culture can be collected by swabbing the nasopharynx, by nasopharyngeal washing, or by nasopharyngeal aspiration.[96,205] In general, nasopharyngeal aspiration gives the highest yield of positive cultures and nasopharyngeal wash is the least sensitive.

B. pertussis and *B. parapertussis* are recovered most easily by direct plating of the specimen from the patient onto selective media.[96,98,245,311] Specific swabs (calcium alginate or Dacron) and media (Regan-Lowe or Bordet-Gengou agar and modified Stainer-Scholte broth) are required, and laboratory personnel should be experienced in isolating the organisms. If cultures cannot be inoculated directly, the use of Regan-Lowe transport medium is recommended. In classic disease, the culture will be positive in approximately 80 percent of cases if the specimen is obtained within 2 weeks of the onset of cough and antibiotics have not been administered previously.[223,397] Direct fluorescent antibody testing has been used for the diagnosis of pertussis caused by *B. pertussis* or *B. parapertussis* during the past 45 years.[333,371,464] It is rapid and inexpensive, but it lacks sensitivity and specificity; it does not employ amplification for sensitivity, and it lacks specificity because of cross reactions with other organisms of the nasopharyngeal flora.[153] Because of the lack of both sensitivity and specificity, its use is no longer recommended for diagnosis.[106,489,535]

Since the late 1980s, numerous PCR assays with primers derived from many different chromosomal regions have been developed for the diagnosis of *B. pertussis*, *B. parapertussis*, *B. holmesii*, and *B. bronchiseptica* infections, and they have been evaluated in multiple studies by comparison with culture and clinically typical pertussis.*

PCR has the advantage of having much higher sensitivity than that of conventional culture. In a prospective study in which swabs for PCR and culture were obtained simultaneously from 555 ill subjects with cough, the use of PCR increased the identification of *B. pertussis* infection almost fourfold, from 28 to 111.[444] Only a few studies have been reported in which the sensitivity and the specificity of PCR for the diagnosis of *B. pertussis* infection were determined by comparison with serologically identified cases.[227,299,302,418,500] In a study that our group performed, we compared PCR results with serologic diagnosis and found that PCR had a sensitivity of 61 percent and a specificity of 88 percent.[163] Similar findings have been noted in other studies.[299,302,419,500] At present, the most commonly used primers for the diagnosis of pertussis include IS 481 and IS 1001.[105,312,333,486] IS 481 occurs in the genomes of *B. pertussis* (>50 copies) and *B. holmesii* (8 to 10 copies) but not in *B. parapertussis*. IS 1001 occurs in the genomes of *B. parapertussis* and *B. holmesii* (~20 copies) but not in *B. pertussis*. The genome of *B. bronchiseptica* generally contains neither IS 481 nor IS 1001. However, in recent studies, *B. bronchiseptica* strains were found to contain IS 1001 in their genomes (in the form of an IS 1001-like element, called hIS 1001).[169,417,486] False-positive results are a potential problem with the use of PCR for establishing the diagnosis of pertussis and other respiratory illnesses.[4,339,371] False-positive results can occur if specimens are opened in the pertussis laboratory before transport to the PCR laboratory.[333] False-positive results also can result from contamination of the air in a room in which the previous patient had pertussis and in a room where pertussis vaccine was administered.[324,485] Moreover, as noted earlier, *B. bronchiseptica* can be mistaken for *B. parapertussis* when the IS 1001 primer is used.[169,417] Therefore, rigorous internal and external laboratory controls are necessary. In addition, because insertion sequence elements are somewhat promiscuous, nucleic acid amplification tests should, whenever possible, be accompanied with conventional culture.

Obtaining a routine laboratory diagnosis of *B. pertussis* infection in adults or in other atypical cases is hampered by the problem that medical care usually is not sought until the third or fourth week of the illness and antibiotics frequently have been administered before the possibility of pertussis was considered.[106,356,447] During the past 25 years, the most significant advance in the diagnosis of pertussis has been the development of ELISA.[333]

Natural infection with *B. pertussis* is followed by a rise in serum concentrations of IgA, IgG, and IgM antibodies to specific antigens of the organism, as well as to preparations of the whole organism.* In contrast to natural infection, primary immunization of children induces mainly IgM and IgG antibodies.

Serologic testing for *B. pertussis* infection in the clinical setting is not well standardized but is widely available in Europe and North America.[106] In the research setting, the use of ELISA contributed significantly to establishing the diagnosis of *B. pertussis* infection in many patients with negative cultures.† Most useful was the determination of IgG and IgA antibodies to PT and FHA. The most reliable proof of acute infection is the demonstration of a significant increase in antibody values between acute-phase and convalescent-phase serum specimens. Frequently, because collection of acute-phase specimens is delayed and, therefore, the acute-phase values already are elevated, significant increases between first and second serum specimens cannot be demonstrated. However, a diagnosis can usually be established on the basis of a high value or values on a single serum specimen.[135,356,447,533,544] Because *B. parapertussis* infection induces cross-reacting antibodies to *B. pertussis* FHA, the use of this antigen alone cannot differentiate *B. pertussis* from *B. parapertussis* infection.[187,463]

Measurement of agglutinating antibodies also is useful for establishing the diagnosis of *B. pertussis* infection, and, because the test is simple, inexpensive, and accurate, it

*References 9, 105, 106, 141, 152, 156, 179, 191, 200, 218, 227, 252, 280, 298, 299, 302, 312, 324, 329, 339, 392, 417-419, 432, 444, 445, 485, 486, 489, 499-501, 535.

can be used in the clinical setting.[135,232,356,397,447] Unfortunately, its sensitivity is low.

Today in clinical practice, the laboratory diagnosis of pertussis should be approached as follows: In all cases in which the cough is of less than 2 weeks' duration in adolescents and adults or 3 weeks' duration in children, a nasopharyngeal specimen should be obtained for culture or PCR. In adults who have had cough for more than 2 weeks' duration, single serum ELISA is the preferred method provided they have not been immunized against pertussis in the previous 12 months.[106] This method also can be used in children if they have not been immunized within a year. At present, many commercial laboratories offer single serum diagnostic tests for *B. pertussis*, and almost all the offered tests lack specificity. Any test that employs the whole organism in the test is fraught with false-positive results. Tests that report specific IgM antibodies also are unreliable. The greatest sensitivity and specificity for the serologic diagnosis of *B. pertussis* infection are achieved by ELISA or an ELISA-like test with the measurement of IgG and IgA antibodies to PT. Single high values of IgG or IgA antibodies to PT are indicative of infection.[333] A sensitive and specific test in North America is available from Focus Diagnostics, Cypress, California.[412] The performances of a number of European commercial serum ELISA kits for the diagnosis of *B. pertussis* illness has been evaluated by Riffelmann and associates.[421] They found that three kits that used PT as the antigen had specificities and sensitivities from 80 percent to 90 percent.

Not all infected persons develop antibody responses to PT. In children, approximately 25 percent lack an adequate response, as do approximately 10 percent of adolescents and adults.[93,463]

An ELISA also has been developed for the detection of IgA antibody to *B. pertussis* in nasopharyngeal secretions and as an indicator of recent infection.[181,186,547] *B. pertussis* IgA appears in nasopharyngeal secretions during the second or third week of illness and persists for at least 3 months.[181] However, the appearance of secretory IgA may be delayed in children younger than 1 year of age.[374] This antibody is not induced by primary parenteral *B. pertussis* vaccination. Detection with the use of ELISA of *B. pertussis* IgA in secretions may be a diagnostic aid in culture-negative patients whose symptoms have persisted for longer than 3 weeks. To our knowledge, this test is not clinically available.

TREATMENT

Several antibiotics have in vitro efficacy against *B. pertussis*.* The first choice for treatment since the 1970s has been oral erythromycin; this ameliorates the symptoms if it is given early during the course of the illness and eliminates the organism from the nasopharynx within a few days, thereby shortening the period of contagiousness.[34] The dose for children is 40 to 50 mg/kg/day given every 6 hours for 14 days; the dose for adults is 2 g/day given every 6 hours for 14 days. A 7-day course of erythromycin estolate was shown in a large study in Canada to be as efficacious as 14 days of treatment.[208] The newer macrolides, azithromycin 10 mg/kg on day 1 and 5 mg/kg on days 2 to 5 as a single dose for 5 days for children and 500 mg on day 1 and 250 mg on days 2 to 5 for adults or clarithromycin 15 to 20 mg/kg/day in two divided doses for 7 days for children and 1 g/day in two doses for 7 days for adults, also can be expected to be effective.[7,67] Although rare, the use of erythromycin in young infants is associated with hypertrophic pyloric stenosis, so parents need to be educated about the symptoms of this potential risk.[62,244,365] Because of this risk, the Centers for Disease Control and Prevention recommends treating neonates with azithromycin rather than erythromycin.[67] Trimethoprim-sulfamethoxazole can be used as an alternative agent in those who cannot tolerate erythromycin.[250] The first erythromycin-resistant strain of *B. pertussis* was isolated from a 2-month-old male infant in Yuma County, Arizona, in June 1994.[296] The isolate was highly resistant, with a minimal inhibitory concentration (MIC) greater than 64 μg/mL (the usual MIC of erythromycin is 0.02 to 0.1 μg/mL). Four more resistant *B. pertussis* strains were recovered from cases in California, Utah, and Minnesota.[196,282,292] In France, macrolide resistance developed during illness in a neonate. In Japan, six *B. pertussis* strains were found to have high level resistance to nalidixic acid and decreased susceptibilities to fluoroquinolones.[391] At present, no evidence of a pattern of emerging macrolide resistance has been seen, but because PCR rather than culture is becoming the diagnostic method of choice in many laboratories, the chance of missing resistant strains is a possible problem.

Patients infected with *B. parapertussis* and *B. holmesii* also can be treated with macrolides, but *B. bronchiseptica* usually is resistant to erythromycin so that alternative therapy is necessary.[333] *B. bronchiseptica* strains usually are sensitive to aminoglycosides, extended-spectrum third-generation penicillins, tetracyclines, quinolones, and trimethoprim-sulfamethoxazole.

Historically, no infectious disease has a greater list of remedies lauded as beneficial but without objective evidence of effectiveness.[36,90] Supportive care includes avoidance of factors that provoke attacks of coughing and maintenance of hydration and nutrition. In the hospital, gentle suction to remove secretions and well-humidified oxygen may be required, particularly in infants with pneumonia and significant respiratory distress. In severe infections in neonates and young infants, assisted ventilation is often necessary.

However, infants who develop pulmonary hypertension with respiratory and cardiovascular failure respond poorly to aggressive therapy (pulmonary artery vasodilators and extracorporeal membrane oxygenation [ECMO]) and have high mortality rates. Because data suggest that the refractory pulmonary hypertension results from the extreme leukocytosis with lymphocytosis, which is always present in fatal cases, our opinion is that leukocyte-reducing measures such as exchange transfusion should be implemented.[138,194,402,431] Exchange transfusion may be

*References 22, 27-29, 34, 67, 246, 249-251.

better than leukofiltration because it removes PT as well as reducing the WBC count.

The use of corticosteroids has received attention in the treatment of pertussis.[36,551] Cortisone treatment in the murine model of pertussis increased the mortality rate.[256] In a study by Roberts and associates,[424] dexamethasone treatment did not shorten the course of hospitalization compared with untreated controls.

The use of salbutamol has also been suggested as having some value, but no benefit was noted in three studies reviewed by Bettiol and coworkers.[36,47] Pillay and Swingler[403] reviewed the symptomatic treatment of pertussis and found no statistically significant benefit for the use of diphenhydramine, dexamethasone, or salbutamol.

PROGNOSIS

The prognosis in pertussis is related to the patient's age. In older children and adults, the prognosis is good, but infants have a significant risk for death and development of encephalopathy.* In addition, long-term follow-up suggests that apnea or seizures at the time of disease in children may be associated with subsequent intellectual impairment.[477] The present availability of pediatric intensive care units and assisted ventilation has reduced the rate of mortality in infants who receive medical care.[228] Unfortunately, many deaths occur outside the hospital. No evidence has shown that pertussis impairs ventilatory function later in life.[266]

PREVENTION

Vaccine Efficacy

Whole-Cell Vaccines

The first pertussis vaccines were developed in the 1920s, and effective vaccines have enjoyed worldwide use since the 1940s.[77,94,96,333] After World War II, extensive vaccine trials were organized by the British Medical Research Council.[340-342] Based on these studies, as well as smaller studies in England, the United States, and other countries, DTP vaccine use became routine in many countries.[164]

The pertussis attack rate was relatively constant in the United States in the prevaccine era between 1922 and 1942. From 1943 to 1976, a 150-fold reduction in the attack rate was noted in association with widespread childhood pertussis immunization.

The existence of a relationship between vaccine use and disease control also was supported by data from England and Wales. The pertussis attack rate declined between 1958 and 1973 and increased dramatically between 1977 and 1983 after a marked decrease occurred in the number of vaccinations administered, beginning in 1974.[77] The attack rate decreased with the widespread use of vaccine and increased when vaccine use decreased. Moreover, the attack rate after the decrease in vaccine use was increased most markedly in the newly susceptible cohort of children younger than 4 years of age.

In the 1980s, numerous household contact studies were performed.[59-61,135,398] In a study from 1982 to 1983 involving 440 household contacts aged 6 months to 9 years, the secondary attack rate in unvaccinated contacts was compared with the rate in children who had received three or more DTP doses. Vaccine efficacy was found to be 91.4 percent. A similar study conducted during the period 1979 to 1981 revealed an efficacy of 82.4 percent.

In another study, Onorato and associates[398] noted that the calculated efficacy varied markedly according to the clinical case definition. Efficacy against any cough was 63 percent, whereas it was 83 percent if a cough duration of 21 or more days was required.

In the 1990s, the most definitive studies of vaccine efficacy of both DTP and DTaP were performed in four countries.* In these trials, the efficacy of the candidate DTaP vaccines was compared with the efficacy of DTP vaccines; the controls were subjects who received DT. With the exception of one lot of one DTP vaccine (Connaught, USA), which had poor immunogenicity, the DTP vaccines were more efficacious than were the DTaP vaccines. The poor efficacy of the Connaught DTP vaccine probably was the result of an unusual low potency lot of this vaccine rather than a generic problem with this vaccine.[333] In a case-control study in the United States, the efficacy of the Connaught vaccine was similar to that of the Wyeth-Lederle DTP vaccine, which, in the controlled trial in Germany, had a high level of efficacy.[40] Finally, in a large comparative trial, the DTP vaccine from England (Evans vaccine) had efficacy greater than those of the three DTaP vaccines with which it was compared.[394]

Acellular Vaccines

Research in the 1970s showed that three *B. pertussis* antigens (PT, FHA, LPS) were liberated into the medium during culture and that these antigens could be concentrated and separated by density gradient centrifugation.[96,238] This finding allowed for the development and production of vaccines by six manufacturers in Japan.[102,279,386,441] All six vaccines had minimal or no endotoxin but different amounts of PT and FHA. In addition, some of the vaccines were found to contain FIM 2 and PRN.

Despite limited proof of efficacy, the six vaccines were put into routine use in Japan in 1981, and they have controlled, to some degree, reported epidemic pertussis during the ensuing decades. However, because adequate data were not available on any single vaccine or on vaccine use in young infants, many extensive trials were performed subsequently in Europe, Africa, and Japan.†

After extensive analysis of the data was conducted on the original efficacy trial in Sweden in the mid 1980s, calculated efficacy was found to vary significantly,

depending on the clinical case definition and the laboratory methods.* Therefore, researchers decided that a universal primary case definition should be developed for use in all subsequent efficacy trials so that different vaccines in different trials could be compared.

A World Health Organization (WHO) committee met in Geneva in January 1991, and a primary case definition was developed.[542] This definition and minor variations of it were used in the efficacy trials in the 1990s. The WHO case definition is as follows: (1) an illness with 21 days or more of spasmodic cough and either culture-confirmed infection with *B. pertussis* or serologic evidence of infection with *B. pertussis* as indicated by a significant rise in IgA or IgG antibody by ELISA against PT or FHA in paired sera or (2) contact with a case of culture-confirmed pertussis in the household with onset within 28 days before or after the onset of cough in the study vaccinee. Not all members of the WHO committee, including one of us (J.D.C.), agreed with this primary case definition because its use results in the elimination of many laboratory-confirmed cases from efficacy calculations.† With this definition, vaccines that lessen the severity of disease but are poor at preventing mild disease will be overrated.

In 1994 and 1995, seven efficacy trials with candidate DTaP vaccines in four countries were completed,‡ and an additional trial in Sweden was completed in 1997.[394] As noted in Table 129-4, the nine vaccines are different in the number of antigens that they contain, as well as in the concentrations of the specific antigens. In all efficacy studies, confounding factors may affect the results. In general, double-blind studies with placebo and whole-cell vaccine controls are ideal. However, placebo control was not ethical in countries in which DTP vaccine was recommended. Therefore, studies in Germany and Senegal used various methods to obtain efficacy data in spite of the lack of a blinded diphtheria-tetanus (DT) toxoid group. Observer bias can affect the results of all studies, including those with double-blind control. For example, a less efficacious vaccine that prevents typical disease but not mild disease can be determined to be more efficacious than it actually is if the study observers believe they "know pertussis" and dismiss atypical cases as being other respiratory tract illnesses and do not obtain cultures or conduct prospective follow-up.[101]

In general, household contact studies, unless they are nested analyses in prospective cohort studies, also are subject to observer bias, and case-control studies result in significantly inflated efficacy percentages.* In cohort studies, observer bias by parents can be reduced by frequent prospective telephone contact with study families. Finally, serologic diagnosis, as well as diagnosis by culture, increases the identification of mild cases, which are more likely to occur in vaccinees than in control subjects.

A summary of the efficacy data for 10 acellular pertussis vaccines evaluated in the 8 trials performed in the 1990s and the earlier 1980s Swedish trial is presented in Table 129-5. The data in this table indicate that three- and four-component vaccines (vaccines containing PRN and FIM as well as PT and FHA) have greater efficacy against *B. pertussis* illness (mild and typical) than do the PT or PT/FHA vaccines. The apparent high efficacy of the two-component vaccine (Tripedia) in the Munich study[300] can be explained by the type of study (case-control study), significant observer bias, the vaccine containing PRN and FIM as well as PT and FHA, and the lack of serologic diagnosis. The final study, done in Stockholm, was a comparative study without a DT

*Efficacy against typical pertussis based on positive culture without serologic analysis.
†Significant observer bias occurred in this trial.[56]
‡Laboratory diagnosis based on culture only; 80 percent efficacy was against illness with cough of 21 or more days, and 93 percent efficacy was against the World Health Organization (WHO) case definition.
§Thirty-one percent efficacy based on 21 days or more of illness with cough; 74 percent efficacy was against the WHO case definition.

control group.[393] In this trial, in which vaccines were administered to children at 3, 5, and 12 months of age, the efficacy of CCL DTaP5 (a five-component vaccine) was significantly better than that of Acelluvax (a three-component vaccine) and was not significantly different from that of the comparative DTP vaccine (Evans vaccine). Acelluvax had greater efficacy than did the two-component vaccine SKB-2.

Follow-up studies of the various efficacy trials have been done in Sweden, Italy, and Germany, and all suggest sustained protection.[199,315,393,438,439] Of particular importance in this regard is the most recent report by Gustafsson and associates,[198] in which members of the large cohort vaccinated at 3, 5, and 12 months in the 1993 to 1996 trial were observed from October 1997 to September 2004. Overall, good protection lasted for approximately 5 years. The tabular data in this report suggest that Acelluvax had efficacy similar to that of CCL DTaP5. However, when all the data from the original trial and the present follow-up data are combined, the overall attack rate in those children who had received CCL DTaP5 was lower (47.5/100,000) than that in children who had received Acelluvax (59.7/100,000). This difference was not significantly different, however. Most notable is that the Evans DTP vaccine had greater sustained efficacy than did either Acelluvax or CCL DTaP5. In summary, it appears that DTaP vaccines that contain PRN have relatively good efficacy for approximately 5 years but that (with the exception of one lot of one DTP vaccine), in general, DTP vaccines are more efficacious.*

Around 2005, two acellular pertussis component, diphtheria, and tetanus toxoid vaccines (Tdap vaccines) became available for use in adolescents and adults.† These two vaccines are Adacel and BOOSTRIX, and their components are presented in Table 129-6. Both these vaccines elicit vigorous antibody responses to the antigens that they contain after a single dose. These responses are significantly greater than those observed in infants at 7 months of age after they have received three doses of the DTaP vaccines (Daptacel and INFANRIX) of the two manufacturers.

In a double-blind efficacy trial in adolescents and adults, an acellular pertussis vaccine (without diphtheria and tetanus toxoids) with the same concentrations of PT, FHA, and PRN as BOOSTRIX had an efficacy of 92 percent.[513] However, the data safety monitoring board allowed the removal of one case in a vaccinee. If this case is included, the efficacy is approximately 78 percent. No similar efficacy trial was done with Adacel or its acellular pertussis components. However, extensive epidemiologic data from Canada, where Adacel has been used since 2003, show a marked reduction of pertussis in adolescents.[271]

The 2010 epidemic of pertussis in California, as well as more recent outbreaks in other states and Australia, has led to a number of studies of Tdap vaccine failure and vaccine effectiveness.[72,414,519,537] In a study by Wei and associates, Tdap vaccine effectiveness in school children 11 years of age and older was 66 percent.[519] However, the sample in this study was small so the result was not statistically significant. In a study of adolescents, Tdap effectiveness was found to be 78 percent.[415]

Adverse Events

Whole-Cell Vaccines

Local reactions and relatively mild systemic complaints are frequent occurrences after pertussis immunization. Less commonly, severe neurologic illness and death have been noted in temporal association with DTP immunization.

The largest study in the United States designed to assess the risk for relatively common and uncommon reactions to pertussis vaccine was performed by Baraff and associates.[18-21,110] This study was conducted between January 1978 and December 1979. Reactions in children who received either DTP or DT immunization were compared. A total of 15,752 DTP immunizations and 784 DT immunizations were given to children aged birth to 6 years of age. These children were evaluated for reactions that occurred within 48 hours of vaccine administration. All common local and systemic reactions occurred more frequently in the DTP recipients than in the DT group. Differences between the common reactions in the two groups were all highly significant ($p < .005$).

Redness at the injection site occurred in 37.4 percent of DTP recipients and in 7.6 percent of DT vaccinees. Fever (≥38° C [100.4° F]) was noted in 46.5 percent of DTP recipients. A temperature of 39° C (102.2° F) or higher occurred in 6.1 percent of DTP recipients, but in only 0.7 percent of DT recipients. Drowsiness, fretfulness, vomiting, anorexia, and persistent crying were other reactions recorded in 3.1 percent (persistent crying) to 53.4 percent (fretfulness) of DTP recipients versus 0.7 percent (persistent crying) to 22.6 percent (fretfulness) of DT vaccinees. In general, rates of local reactions, but not those of systemic reactions (except fever), increase from dose to dose in an immunization series.

In addition to these reactions, 0.1 percent of DTP recipients in this study were reported by the parents to have a high-pitched, unusual cry; 0.06 percent had convulsions, and 0.06 percent had hypotonic-hyporesponsive episodes (shock, collapse). No children in the control group (DT recipients) had similar reactions; however, the control group was of modest size (784 DT recipients), so statistical significance could not be assigned to any of these relatively uncommon events.

Because convulsions in young children are the result of many different etiologic factors, the cause-and-effect relationship with pertussis vaccine is less clear. However, inasmuch as fever develops in almost half of all DTP vaccinees and febrile convulsions are not uncommon events, a reasonable assumption is that many convulsions that occur in temporal association with DTP vaccination are induced by the immunization. Three studies have noted a significant association between pertussis immunization and febrile convulsions.[23,453,510] Approximately 1 per 1000 vaccinees older than 6 months of age will have a first febrile seizure after receiving pertussis immunization. The concomitant use of acetaminophen (15 mg/kg per dose at the time of immunization and every 4 hours for 24 hours) and DTP vaccine has been suggested as a means of reducing the incidence of febrile convulsions in vaccinees.[295]

Neurologic disease and death occurring in temporal association with pertussis immunization have been of major concern throughout the vaccine era. During the past 60 years of the 20th century, several case series and individual cases of neurologic illness occurring after receipt of pertussis immunization were reported; by 1979, more than 1000 cases of alleged neurologic damage induced by pertussis vaccine were reported.* Few of these reports had evidence of an adequate search for other possible causes of the neurologic disease, and in none were data available for rate calculations.

From 1967 to 1980, several attempts were made to determine the frequency of neurologic disease after receipt of pertussis immunization.† However, because controls were not included in any of the population evaluations, all rate estimates included children with temporally related events that had other causes.

A carefully designed prospective case-control study (National Childhood Encephalopathy Study [NCES]) of all hospital admissions of children aged 2 to 35 months with acute serious neurologic disorders in England, Wales, and Scotland was undertaken between 1976 and 1979.‡ The results of this study for the first time revealed an apparent statistical association between pertussis immunization and neurologic illness. Researchers found that a child who had received DTP vaccine within the previous 3 to 7 days was two to five times more likely to have neurologic disease than was a child who was not immunized during the same interval. The causal relationship between DTP immunization and neurologic illness noted in this study must be questioned, however,

*References 33, 53, 75, 77, 285, 328, 531.
†References 3, 77, 143, 144, 166, 214, 467, 476.
‡References 5, 31, 318, 347-350.

because both cases and controls had an equal frequency of immunization during the month preceding the index date. A more appropriate interpretation of the results is that they do not indicate cause and effect; rather, the DTP immunization calls attention to or brings out something that will occur anyway but just moves it forward in time ("trigger effect").[78,79]

Cases of infantile spasms, an identifiable seizure disorder of infancy, usually occur in the 6-month period from 2 to 7 months of age; therefore, that some cases occur after DTP immunization is not surprising. Simple calculations indicate that approximately 12 percent of all patients destined to have infantile spasms between 2 and 7 months of age will have an onset of illness within 7 days after receiving DTP immunization. The temporal association between DTP immunization and infantile spasms has led many people to assume a cause-and-effect relationship. However, controlled data from the NCES in Great Britain provide strong evidence against a causative role for pertussis vaccine in infantile spasms.[31] In another study, Melchior[343] in Denmark noted that the time of onset of infantile spasms was not altered when the time of pertussis immunization was changed from 5, 6, 7, and 15 months of age to 5 weeks, 9 weeks, and 10 months of age. In both periods, 42 percent of patients had their onset during the first 4 months of life.

Data from the NCES were reanalyzed with the exclusion of cases of infantile spasms.[349,350] From these analyses, the risk for permanent brain damage occurring from pertussis immunization has been suggested to be 1 per 330,000 vaccine doses and the risk for any encephalopathy has been estimated to be 1 per 140,000 vaccinations. However, a review of the NCES data by other investigators indicates that both rate estimates are incorrect. Specifically, Stephenson[466] showed that the 1 per 140,000 rate for all encephalopathy is an artifact resulting from the inclusion of 9 children with febrile convulsions. Similarly, MacRae[317] noted that the increased relative risk that was observed within 7 days of receiving immunization (which was used to calculate the risk for brain damage of 1 per 330,000 immunizations) was offset by a decreased relative risk over the subsequent 3-week period. This finding, similar to the original study data and the infantile spasm data, indicates not a cause-and-effect relationship but rather a redistribution of events over time.

In the United States, the major neurologic illness that was noted in temporal association with DTP immunization was the first seizure of what turned out to be severe epilepsy. By chance alone, this association may occur 400 times a year in the United States. Four carefully performed studies that included approximately 330,000 children and 1 million immunizations have examined the possibility that pertussis immunization is a causative factor in epilepsy; no evidence of a causative role has been found.* More recently, two large studies in the United States and Canada found no evidence of a causal association with DTP immunization and encephalopathy.[363,416]

Similar to infantile spasms, SIDS also occurs in early life; therefore, that cases are noted to occur after administration of DTP immunization again is not surprising. Hoffman and associates[242] performed an extensive prospective case-control study of risk factors in SIDS from October 1978 through December 1979. In this study of 800 cases, investigators found that DTP immunization was not a risk factor for development of the syndrome. Other good, controlled studies have yielded similar results.[96,189] No evidence has demonstrated that DTP vaccinees have an increased risk for developing asthma later in life.[235]

Acellular Vaccines

An extensive amount of reactogenicity information was generated in phase 2 and phase 3 studies with all licensed DTaP vaccines.* Because endotoxin has been removed from all DTaP vaccines, one is not surprised that all are less reactogenic than are DTP vaccines. In a double-blind study, the reactogenicity of 13 DTaP vaccines was presented and was compared with the reactogenicity of a DTP vaccine.[134] This study involved 2200 infants; 113 to 217 received an acellular product, and 370 received the whole-cell vaccine. Study participants received three doses of vaccine at 2, 4, and 6 months of age. Overall, all monitored reactions except vomiting occurred less frequently and were less severe in DTaP recipients than in DTP recipients. Specific results from this study are presented in Table 129-6. As can be seen, local redness and swelling and fever increased in frequency from the first to the third dose, whereas the complaint of drowsiness decreased.

In our efficacy trial in Germany with Acel-Immune, we monitored reactions in more than 8000 children after receipt of four doses of vaccine at 3, 4½, 6, and 15 to 18 months.[448,493] For the first three vaccine doses, the findings were similar to those noted in Table 129-7. After the fourth dose, the frequency of occurrence of local erythema and induration and fever increased considerably in comparison with their frequencies after the third dose. Ten percent of DTaP recipients had local erythema of 2.4 cm or greater, and 28 percent had temperatures of 38° C or higher. Other investigators also noted an increased frequency and severity of local reactions occurring after administration of the fourth and fifth doses of DTaP vaccines.[223,261,401,420,449] Of particular concern is the observation of extensive swelling of the thigh with booster doses of some DTaP vaccines.[420,449] Rennels and associates[420] found that this swelling occurred more commonly after immunization with DTaP vaccines containing high amounts of diphtheria toxoid. With Acel-Immune, a vaccine with a low diphtheria toxoid content, we noted that 15.4 percent of subjects had induration of more than 5 cm but less than 10 cm after receiving a fifth dose; swelling of the entire limb was not noted.[223]

In five of the 1990s efficacy trials, the occurrence of less common, more severe events (persistent crying, seizures, and hypotonic-hyporesponsive episodes) was monitored. A summary of these data is presented in Table 129-8. As can be seen, temporally related persistent crying, hypotonic-hyporesponsive episodes, and seizures were rare events after receipt of immunization with DTaP

vaccines. In a large active surveillance program (IMPACT), researchers found that risks of having febrile seizures and hypotonic-hyporesponsive episodes after receiving pertussis-containing vaccines decreased significantly after the introduction of DTaP vaccines in Canada.[291] In a Vaccine Safety Datalink study, Huang and coworkers[254] did not observe an increased risk for seizures in children 6 weeks to 23 months of age after DTaP vaccination.

Schedules and Contraindications

Immunization schedules with whole-cell vaccines have varied throughout the world and to some measure were determined by concern relating to true and perceived reactions.[77,96,146]An immunization schedule involving only three doses given to infants at 2, 3, and 4 months of age was quite effective in controlling pertussis-related morbidity and mortality in the United Kingdom.[498] However, the five-dose schedule used in the United States resulted in lower attack rates in preschool- and school-aged children.[77,96]

The recommendation for the DTaP vaccine in the United States is that it be given in the same five-dose schedule as previously recommended for DTP vaccines.[7,63] However, follow-up data from the 1990s efficacy trials, as well as reactogenicity data, suggested that use of this "one size fits all" approach could be modified.* Our findings with Acel-Immune suggested that the present five-dose schedule was appropriate.[315,463] Conversely, data from other trials suggested that administration of the fourth dose of some vaccines could be postponed until the child was 4 to 6 years of age, or the third dose could be moved back to the child's second year of life.† These changes would not be expected to decrease efficacy but would decrease troubling local reactions with booster doses. It should be pointed out, however, that the follow-up data in the just-mentioned studies employed passive surveillance techniques and therefore pertussis attack rates in DTaP recipients were

*References 188, 198, 393, 438, 439, 449, 484, 490.
†References 199, 393, 394, 438, 439, 484, 490.

likely underestimated. Recent data from the 2010 California epidemic show a yearly increase in vaccine failures after the fifth dose of DTaP.[92,532]

Acellular pertussis component quadrivalent (DTaP, IPV), pentavalent (DTaP, IPV, HBV; DTaP, IPV, Hib), and hexavalent (DTaP, IPV, HBV, Hib) vaccines have been developed and are available in many countries.[146] In the United States, the following multicomponent vaccines are available: DTaP/Hib (TriHIBit for the fourth dose of DTaP and Hib series), DTaP/IPV/HBV (PEDIARIX), and DTaP, IPV, Hib (Pentacel). In general, multicomponent vaccine use should be encouraged to reduce the number of injections that a child receives.[7]

In addition to providing childhood immunization, the availability of adolescent and adult Tdap vaccines allows the vaccination of adolescents and adults to be conducted.* At present, the schedule for the use of Tdap vaccines varies in different countries.[167,168,221] The most common recommendation is for universal immunization of preadolescents and adolescents and the selective immunization of adults. However, our opinion has been that a universal program involving all preadolescents or adolescents and adults every 10 years will be necessary to prevent the transmission of *B. pertussis* effectively to unimmunized infants and to prevent the continued circulation of *B. pertussis* in a population. Because at present no country has an effective program for universal immunization of adults and no country is likely to achieve a universal Tdap booster program with reasonable compliance and because adults are the main source of pertussis in young infants, various cocooning programs have been or are being established.[7,71,192] These programs include postpartum immunization of the mother and, if possible, the father, attempts to vaccinate grandparents, and immunization of mothers-to-be during the second or third trimesters of pregnancy. Also considered is lowering the age of infant immunization, including a dose shortly after birth.† All of these cocooning programs have numerous logistical difficulties.

We believe the two most promising approaches are immunization of the mother-to-be in the second and third trimesters of pregnancy and starting infant immunization at birth. Immunizing the pregnant woman should be easy because it fits into routine obstetric care. However, a problem arises in the woman who has multiple pregnancies because repeated doses with a vaccine (Tdap) with full-strength tetanus toxoid could cause significant reactions.

The immunization of infants at birth followed by an accelerated schedule should provide some early protection and prevent deaths. Because some studies of early immunization have shown a suppression of the overall response to the vaccine antigens compared with a more delayed schedule, early immunization has, in recent years, not been looked upon favorably.[20,51] However, recent epidemics suggest that there may be reason for change.

Over the years, pertussis vaccine recommendations have undergone many changes. In particular, contraindications to pertussis immunization are evolving continually. An important note, however, is that few scientific data support any of the present contraindications. The primary goal of national immunization programs is to vaccinate all infants, children, and now adolescents and adults. If excessive contraindications and their overinterpretation lead to a large number of unimmunized persons, the programs will fail and the children in greatest need of protection will contract pertussis. In the United States, the most recent recommendations of the Committee on Infectious Diseases of the American Academy of Pediatrics generally should be followed.[7] However, individual case-by-case decisions often need to be made.

Isolation and Prophylactic Measures

Erythromycin, azithromycin, or clarithromycin treatment in the index case shortens the duration of communicability of the organisms and thus limits spread of the disease. During the first few days of treatment, contact with susceptible persons should be avoided. In general, close contacts (household members, those in daycare centers, playmates) of the index case should be protected from infection. Such protection can be implemented by the prophylactic use of erythromycin for 14 days, azithromycin for 5 days, or clarithromycin for 7 days.[7,67,333,465] Active immunization of all exposed persons (children, adolescents, and adults) who are not adequately vaccinated also should be conducted.

The use of prophylactic antibiotics in adolescents and adults in exposure situations such as classrooms and hospital settings frequently is recommended. This approach often involves many people and considerable expense.

In our experience, the side effects of erythromycin and other macrolides are such that adult compliance is poor. Therefore, our opinion is that erythromycin and other macrolides should generally not be used prophylactically in these large group settings but only for treatment at the first sign of respiratory illness in those exposed.

OTHER *BORDETELLA* INFECTIONS

Bordetella parapertussis Infection

B. parapertussis infection in children can cause unrecognized infection, mild pertussis, or typical pertussis.[333] We studied 38 children with *B. parapertussis* illnesses and compared their illnesses with those occurring in 76 children with *B. pertussis* illnesses.[231] The results were as follows *(B. pertussis/B. parapertussis)*, in percentages: cough for longer than 4 weeks, 57 percent/37 percent ($p = .06$); whooping, 80 percent/59 percent ($p = .07$); whooping for longer than 2 weeks, 26 percent/18 percent ($p = .05$); paroxysms, 90 percent/83 percent; posttussive vomiting, 47 percent/42 percent; and mean leukocyte and lymphocyte counts, 12,500/mm^3 and 7,600/mm^3, and 7,800/mm^3 and 3,500/mm^3 ($p < .0001$), respectively. In another study in Italy, children with *B. parapertussis* infection had the following rates of findings: cough, 100 percent; paroxysms, 76 percent; whooping, 33 percent; posttussive vomiting, 42 percent; apnea, 29 percent; and cyanosis, 12 percent.[330] All of these rates except cough

and paroxysms were lower in children with *B. parapertussis* infections than in children with *B. pertussis* infections. Concomitant infections with *B. pertussis* and *B. parapertussis* are not rare.[247,259,344]

Before and during the early pertussis vaccine era, pertussis caused by *B. parapertussis* was considerably less common than that caused by *B. pertussis*.[333] For example, during a 16-year period in the Grand Rapids area of Michigan, 4483 cases of pertussis were caused by *B. pertussis* and 106 cases were caused by *B. parapertussis*.[150] More recently, during the DTaP vaccine efficacy trials in Europe, the comparative rates of illness caused by *B. pertussis* or *B. parapertussis* were examined. In our trial in Germany, the rate of pertussis caused by *B. parapertussis* infection in control children was 0.9 cases per 100 person-years.[463] Of 130 culture-confirmed cases, 21 percent were caused by *B. parapertussis*. The percentage of cases caused by *B. parapertussis* in five other trials varied from 2.1 to 20 percent.[330]

Until recently, reported pertussis caused by *B. parapertussis* has been an uncommon finding in the United States. However, during 2004 and 2005, 493 culture-positive cases of pertussis were noted by the Wisconsin State Laboratory of Hygiene.[382] Of these cases, 14 percent were caused by *B. parapertussis*. During the period 2008 to 2010 clinical specimens from 9 states were tested by PCR for *B. pertussis* and *B. parapertussis* in a commercial laboratory.[105] Of the positive samples, 13.99 percent were identified as *B. parapertussis*. The *B. parapertussis*–positive samples had no seasonal periodicity, whereas the *B. pertussis*–positive samples occurred between weeks 22 and 38 each year. In contrast to the findings in the United States, Kurova and associates[286] noted *B. parapertussis* cyclic peaks in 1995, 2000, 2003, and 2007.

Bordetella bronchiseptica Infection

B. bronchiseptica causes respiratory tract infections in at least 18 different mammals.[118] Most notable are atrophic rhinitis in pigs, kennel cough (rhinotracheitis) in dogs, and bronchopneumonia in rabbits and other laboratory animals.

In 1911, McGowan[337] observed that laboratory workers exposed to various animals with *B. bronchiseptica* infections on occasion had respiratory tract illness. In 1926, a 5-year-old girl with a pertussis-like illness was found to be infected with *B. bronchiseptica*.[50] Her illness began 10 to 12 days after she had been given a rabbit with mild "snuffles." Otherwise healthy children who became infected with *B. bronchiseptica* after being exposed to farm animals or pets usually have pertussis-like illnesses.[333]

In 2008, Rath and coworkers[415] described an infant who had recurrent episodes of pertussis-like illness due to *B. bronchiseptica* that cleared after imipenem therapy. In another recent study, another immunocompetent infant with recurrent pertussis-like illness was described.[129]

Occasional infections in humans have been noted during the past 40 years, with the majority occurring in immunocompromised adults, including patients with acquired immunodeficiency syndrome.[6,142,525,541] Respiratory tract infections have ranged from mild upper respiratory tract illnesses to pneumonia. In patients with acquired immunodeficiency syndrome, the pneumonia frequently is cavitary. Sinusitis and bronchitis also occur.

Bordetella hinzii Infection

B. hinzii has, on occasion, been recovered from sputum cultures from patients with cystic fibrosis.[173,459] The role of these isolates in pulmonary disease in cystic fibrosis is unknown. Some isolates are likely transient colonization,[459] but one adult patient had the organism recovered during pulmonary exacerbations throughout a 3-year period.[173] *B. hinzii* has been found to cause septicemia and cholangitis in adult patients with immunodeficiencies.[16,116,171,253,272]

Bordetella holmesii Infection

In 1999, Yih and associates[545] reported the isolation of *B. holmesii* from the nasopharyngeal specimens of 33 patients suspected of having pertussis. Twenty-three of the cases were investigated further, and 19 (82%) of these patients were adolescents, 2 (9%) were adults, and 2 (9%) were children. All had cough: 61 percent had paroxysms, 26 percent had posttussive vomiting, and 9 percent had whoop. More recently, *B. holmesii* has been isolated from nasopharyngeal specimens from patients with pertussis-like illnesses in France, Canada, and the Netherlands.[361,385] The incidence of pertussis-like illness due to *B. holmesii* is unknown. *B. holmesii* contains IS 481 and IS 1001. These two insertion sequence elements are routinely used to diagnose *B. pertussis* and *B. parapertussis*, respectively.[105,310,486] If both IS 481 and IS1001 are positive, then it is thought the illness is due to *B. holmesii*. However, because infection with both *B. pertussis* and *B. parapertussis* can occur, dual positives can be either *B. holmesii* or mixed infections with *B. pertussis* and *B. parapertussis*.[105]

B. holmesii has been noted as a cause of meningitis in a 12-year-old anorectic girl, the cause of bacteremia in four asplenic children, the cause of pneumonia in a 15-year old with relapsing nephrotic syndrome, and the cause of septic arthritis in a 15-year-old boy with chronic hemolytic anemia.[140,359,400,497] This agent has also been a cause of bacteremia in children with sickle-cell disease.[335]

B. holmesii also has been isolated from a 10-month-old boy with bacteremia and from patients with septicemia, endocarditis, and respiratory failure.[364,482] In adults, *B. holmesii* has been a cause of prosthetic valve endocarditis, pericarditis in a patient with lymphoma, and meningitis in an asplenic patient with systemic lupus erythematosus.[268,308,377]

Bordetella trematum Infection

B. trematum has been isolated from wounds and ear infections.[126,503]

Bordetella petrii Infection

In adults, *Bordetella petrii* has been associated with suppurative mastoiditis, bronchiectasis, and mandibular osteomyelitis.[172,290,461]

Bordetella avium Infection

Bordetella avium is an avian pathogen, but recently it has been recovered from an adult with pneumonia. Additionally, a *B. avium*-like strain was recovered from an adult with a 4-month history of productive cough.[215]

CHAPTER 130

Calymmatobacterium granulomatis

Mariam R. Chacko

Calymmatobacterium granulomatis has been renamed *Klebsiella granulomatis* and is the causative organism for the genital ulcer disease granuloma inguinale.[8,51] Granuloma inguinale has been known through the years by many different names, the most common being granuloma inguinale, donovanosis, and granuloma venereum.[35]

THE ORGANISM

In 1905, *C. granulomatis* was isolated in India by Donovan. It is an encapsulated gram-negative rod measuring 1.5 × 0.7 μm. *C. granulomatis* was considered a unique species distinct from other related organisms belonging to the subclass Proteobacteria.[24,34,35] However, because of difficulties in growing the organism the biochemical and bacteriologic characteristics of the organism had not been identified.[34,35] In recent studies using DNA hybridization techniques and 16S rDNA sequencing, the position of *C. granulomatis* within the *Klebsiella* genus closest to *K. pneumoniae* has been confirmed. Thus, the organism has now been reclassified under the genus *Klebsiella*.

Study of the organism reveals a complex cell envelope. In addition to having regular bacterial structures such as a mesosome, ribosomes, and nuclear material, the cytoplasm contains electron-dense granules; transmission electron microscopy shows an outer membrane, middle electron-opaque layer, and an inner plasma membrane. The organisms are enclosed mainly in large histiocytic cells and occasionally in polymorphonuclear cells and plasma cells. They multiply intracellularly to approximately 30 in number and eventually cause cell rupture.[9,35]

EPIDEMIOLOGY

Granuloma inguinale occurs predominantly in young and older adults, 20 to 40 years of age, and is a cause of genital ulcerative disease in tropical and subtropical regions of the world; it is now mainly seen in sporadic cases in Papua New Guinea, South Africa, India, Brazil, and Australia.[10,33,49] In the preantibiotic era granuloma inguinale was prevalent in many areas of the world.[33] As with all genital ulcerative diseases, granuloma inguinale has been given greater attention as a risk factor for development of human immunodeficiency virus (HIV) infection.[41] In South Africa, the prevalence of granuloma inguinale in patients with genital ulcer disease is reported to be approximately 10 percent.[38] A resurgence of the disease was reported in the late 1980s in Durban, South Africa. After a rapid test for donovanosis was introduced in the early 1990s, the number of cases reported by the Durban Health Department in South Africa increased substantially.[31] As a result of the availability of the rapid test and implementation of an HIV/sexually transmitted infections (STIs) initiative, the number of new cases of donovanosis in Australia decreased dramatically; five cases were reported in 2005.[3] In 1994, after 4 decades, a case of granuloma inguinale was reported in China.[16]

The prevalence of granuloma inguinale increased in developed countries in the 1990s, especially among migrant and poor people living in metropolitan areas. For example, three cases of granuloma inguinale were reported in Rome between 1993 and 2001, with most of them diagnosed in 2000 and 2001.[30] In 1992, three unrelated cases of granuloma inguinale, seen within a period of a few weeks, were reported in Toronto; two occurred in immigrants, and one occurred in a native-born Canadian. The first patient was a recent immigrant from El Salvador, and the second patient had immigrated several years previously and had a history of sexual activity with a Jamaican who had immigrated recently. The sexual partner of the third case had come from Turkey.[21] In 2007, donovanosis and syphilis were diagnosed in a single genital ulcer at a London clinic in a Jamaican heterosexual male known to have herpes.[45]

In 1947, the estimated population prevalence of granuloma inguinale in the United States was 5000 to 10,000[35]; more than 1000 cases per year were reported to the Centers for Disease Control and Prevention (CDC). Since the antibiotic era, the prevalence of this disease has declined rapidly and no cases have been reported in recent years through standard surveillance reports by the CDC. During the past 2 decades, granuloma inguinale has been reported predominantly through case reports; Growden and colleagues,[19] in a 1984 case report, provided national data obtained from the local health departments; 75 cases were reported in 1977 and 17 cases in 1982. This report described a case of a white 18-year-old woman in California in 1985 with a 10-month history of vulvar ulceration and a Giemsa stain positive for Donovan bodies.[19] In 1991, nongenital granuloma inguinale was diagnosed in a man in Texas with testicular carcinoma.[29] More recent case reports have been published from Chicago in 2006[43] and Charlottesville, Virginia in 2009.[1] Although the prevalence of the disease is low, this disease needs to be suspected in North America and Europe because of international travel and immigration.

Granuloma inguinale is a rare occurrence in children. In the early 1950s, 4 percent of 1- to 4-year-old children in a Papua New Guinea population were found to have granuloma inguinale. Although the mode of transmission

in adolescents and adults is considered to be sexual, the mode of transmission of the disease in these children was thought to be by skin-to-skin contact from sitting on the laps of infected adults.[35] Cases published since 1997 report otitis media, mastoiditis, neck mass, and cervical lymphadenopathy as the initial manifestations of donovanosis in infants and children.[4,17,18] The modes of transmission in these cases are thought to be perinatal and by skin-to-skin contact.[4,17,18]

Granuloma inguinale usually occurs more commonly in male than in female patients. However, in adolescents, the disease can develop more commonly in girls than in boys; a reflection of sexual activity between adolescent girls and adult men.[32] The risk factors and mode of transmission of granuloma inguinale are not clear. The disease generally is considered sexually transmitted and has been diagnosed in 12 to 50 percent of marital or steady sexual partners.[35,38] However, in many cases, granuloma inguinale cannot be detected in the sexual partners of infected persons. Anal intercourse also has been associated with rectal and penile lesions of granuloma inguinale.[26] O'Farrell and associates[39] studied the patterns of sexual behavior in Zulu men and women with genital ulcer disease and found that patients with granuloma inguinale and secondary syphilis, despite the presence of ulcers, were more likely than were patients with other genital ulcer diseases to have had sexual intercourse. Studies reported from India and South Africa have noted a preponderance of granuloma inguinale cases in uncircumcised male patients with poor genital hygiene.[32,35]

Coexistence of granuloma inguinale with other STIs occurs commonly. Syphilis has been described in as many as 23 percent of patients with granuloma inguinale. In one report, HIV-1 antibodies were found in as many as 8 percent of male patients with granuloma inguinale.[29,41]

PATHOGENESIS AND PATHOLOGY

The primary lesion in granuloma inguinale is an indurated nodule that erodes through the skin and becomes a granulomatous heaped ulcer. Adjacent lesions form and eventually coalesce, especially in the perineal area. Secondary infection of lesions may occur and may aggravate the tissue destruction and cause scarring. *C. granulomatis* organisms invade mononuclear endothelial cells. Extensive acanthosis and dense dermal infiltrates of mainly plasma cells and histiocytes have been observed in the indurated nodules. Polymorphonuclear cell infiltration also occurs, but lymphocytes are rare findings when secondary infection develops. The pathognomonic feature of granuloma inguinale is a large, infected mononuclear cell, 25 to 90 μm in diameter that contains many intracytoplasmic cysts filled with deep-staining Donovan bodies. Metastatic spread to the bones, joints, liver, and lymphatics occasionally occurs.[35]

A possible link between human leukocyte antigen (HLA)-B57 and granuloma inguinale infection may exist; class I, class II, and DQ antigens have been detected in the genital ulcers of individuals with granuloma inguinale.[36] Circulating lymphocytes and tissue-level lymphocyte subpopulations in granuloma inguinale have been studied.[47,48] T-lymphocyte and B-lymphocyte infiltration in tissues is almost identical, without any significant difference in ulcerogranulomatous and hypertrophic variants of granuloma inguinale. Total leukocyte, absolute lymphocyte, and total T lymphocytes counts; CD4, CD8, and CD22 levels; and the CD4/CD8 ratio are all increased significantly in the ulcerogranulomatous variant of granuloma inguinale. In contrast, the hypertrophic variant causes a significant elevation only in the CD4/CD8 ratio. This finding suggests a greater cell-mediated immune response in the ulcerogranulomatous variant of granuloma inguinale and is consistent with the paucity of Donovan bodies in smears obtained from patients with this variant.[47,48]

CLINICAL MANIFESTATIONS

The incubation period of granuloma inguinale usually is less than 2 weeks but may be as long as 3 months. The disease begins as one or more subcutaneous nodules that erode through the skin to produce clean, large, beefy-red, granulomatous ulcers that bleed easily. The lesions are sharply defined and painless, and the ulcers feel hard when palpated. The disease usually is limited to local tissue; therefore, constitutional symptoms are unlikely to be present. Autoinoculation is a common manifestation that produces "kissing" lesions. The genitalia are involved in 90 percent of cases, the inguinal region in 10 percent, the anal region in 5 to 10 percent, and extragenital sites, usually involving the head and neck, in 1 to 5 percent. Regional (inguinal) lymphadenopathy is not associated with granuloma inguinale.

The morphology of the cutaneous lesions of granuloma inguinale can vary, depending on the stage of the disease. The exuberant or hypertrophic stage appears before secondary infection develops. It consists of large, vegetating masses with overgrowth of granulation tissue, usually in the perianal region. The ulcerative stage is accompanied by secondary infection. In this stage, large, spreading, shallow necrotic ulcers with a foul odor may be noted. The cicatricial stage results after prolonged healing and is characterized by fibrosis, scarring, depigmentation, keloid formation, elephantiasis, and stenosis of the vagina, urethra, and anus. In patients in Durban, ulcerogranulomatous lesions occurred far more commonly than did hypertrophic and necrotic lesions. Although lymphadenopathy is an unusual occurrence in granuloma inguinale, pseudobuboes and pseudoelephantiasis of the genitals (massive edema) may be seen. Pseudobuboes are the result of deep, inguinal granulomata; pseudoelephantiasis is caused by cutaneous extension of lesions and inflammation.[13,29,35]

In male patients, lesions usually occur on the prepuce and also can occur on the coronal sulcus and frenulum of the penis.[10,34,35] The most common clinical manifestation is vulvar ulceration in pregnant (88%) and nonpregnant women (46%).[2] Genital tract bleeding is the next most common finding in nonpregnant women (20%). Multiple sites of genital ulceration (i.e., vulva, vagina, and cervix) have been noted only in nonpregnant women (Fig. 130-1).[1,13,32,34] Extragenital sites may be involved in up to 6

FIGURE 130-1 ■ Granuloma inguinale.

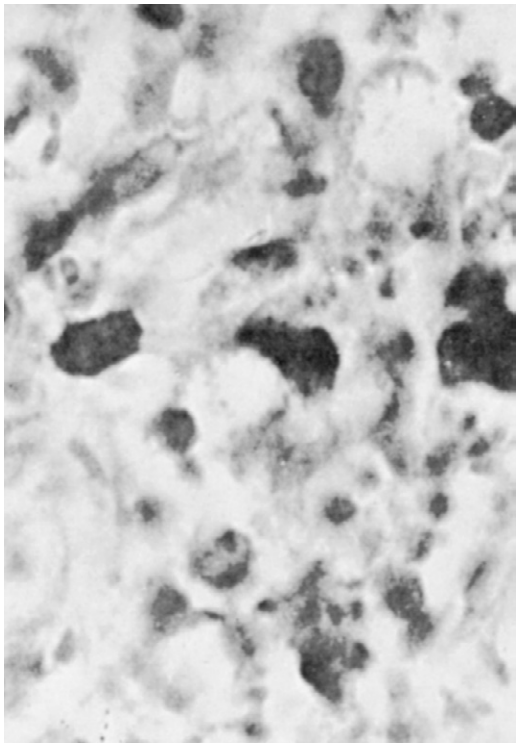

FIGURE 130-2 ■ Donovan bodies.

percent of cases, through hematogenous spread, and have been reported in the mouth, chin, axillae, abdomen, pelvic cavity, and foot.* These distant sites usually are associated with a primary lesion in the genital area.[35] Lesions in the oral cavity have been described after apparently successful treatment of genital lesions.[12] Donovanosis ulcers may take longer to heal in HIV-positive individuals, and greater destruction of tissue may be noted as well.[34,35]

In endemic areas, unusual manifestations of granuloma inguinale may cause confusion with a wide variety of diseases and can result in misdiagnosis. The differential diagnosis includes carcinoma, secondary syphilis, necrotic ulcerations of amebiasis, tuberculosis, and filariasis. In addition, secondary infection can confuse the diagnosis.[20,35]

DIAGNOSIS

Generally, granuloma inguinale is diagnosed on clinical grounds. The accuracy of a clinical diagnosis of granuloma inguinale can be as high as 63 percent in male patients and 83 percent in female patients. In contrast to other genital ulcers, the ulcers are larger in granuloma inguinale, are painless, bleed easily to touch, and usually are not associated with inguinal lymphadenopathy.[40,44]

The diagnosis of granuloma inguinale can be confirmed by identification of dark-staining Donovan bodies in large, histiocytic cells on a stained crush specimen from the lesion (Fig. 130-2). The common stain used to identify Donovan bodies is Wright-Giemsa or Warthin-Starry blue-black stain. A modified Giemsa stain (Rapi-Diff) can yield rapid results in a busy clinic.[35] Donovan bodies have been identified on Papanicolaou smears from the cervix.[11] Examination of appropriately stained specimens from active lesions remains the most reliable diagnostic test. Light-microscopic examination of biopsy specimens that have been fixed in formalin and embedded in wax is less reliable. Donovan bodies rarely are seen by this method.[35,40]

If donovanosis is suspected, a swab for this condition should be taken first, before swabs for other organisms, so that an adequate amount of cellular material can be obtained.[23,35,37] When *C. granulomatis* organisms are likely to be scarce or when smear or crush specimens are likely to be nondiagnostic, obtaining a biopsy of the lesion should be considered. Accordingly, a biopsy specimen, preferably stained with Giemsa or silver, is recommended in very early, very sclerotic, or heavily superinfected specimens.[23,35,37]

Successful isolation of *C. granulomatis* by culture on human epithelial cell lines with a modified *Chlamydia* culture technique has been reported from South Africa and Australia.[5] Polymerase chain reaction (PCR) techniques for *C. granulomatis* also have been developed and further refined into a colorimetric detection system for use in diagnostic laboratories. A genital ulcer disease multiplex PCR test has been developed in Australia using an in-house nucleic acid amplification technique that includes *C. granulomatis* primers.[35] However, no FDA-cleared molecular tests for detection of *C. granulomatis* DNA exist yet in the United States but can be in a laboratory that has conducted a *Clinical Laboratories Improvement Amendments* verification study.[8]

Serologic and skin tests for granuloma inguinale are highly sensitive but not specific. A serologic test using

*References 12, 14, 25, 27, 35, 42, 46, 50.

the indirect immunofluorescence technique has been evaluated and found to have a sensitivity of 100 percent, a specificity of 98 percent, a positive predictive value of 89 percent, and a negative predictive value of 100 percent in diagnosing granuloma inguinale. In the absence of culture methods for *C. granulomatis*, this test may prove helpful in the diagnosis of established lesions and not early ulcers.[15]

The CDC STI surveillance case definition for granuloma inguinale of a confirmed case is a clinically compatible case that is laboratory confirmed. The clinical description of a clinically compatible case is a slowly progressive ulcerative disease of the skin and lymphatics of the genital and perianal area caused by infection with *C. granulomatis*. A clinically compatible case would have one or more painless or minimally painful granulomatous lesions in the anogenital area. The laboratory criteria for diagnosis are demonstration of intracytoplasmic Donovan bodies in Wright- or Giemsa-stained smears or biopsies of granulation tissue.[7]

TREATMENT

Antibiotics with strong activity against *C. granulomatis* are those effective in the treatment of gram-negative bacilli or those whose lipid solubility ensures good intracellular penetration. The CDC recommends treatment of adults and adolescents with doxycycline 100 mg orally twice per day for a minimum of 3 weeks and until lesions are healed.[8] Alternative regimens include the following: azithromycin 1 g orally weekly for at least 3 weeks, ciprofloxacin 750 mg orally twice per day for at least 3 weeks, erythromycin, 500 mg orally four times per day for at least 3 weeks, or trimethoprim-sulfamethoxazole one double-strength tablet (160 mg/800 mg) orally twice per day for at least 3 weeks.[8] Children can be treated with a short course of oral azithromycin suspension 20 mg/kg/day, trimethoprim-sulfamethoxazole (10 mg/kg/day trimethoprim), or erythromycin 30 to 50 mg/kg/day.[8] Clinical response to antibiotics should be noted within a week of treatment; the lesions should become paler and less friable. After a week of treatment, the lesions become smaller, and total healing of the area takes 3 to 5 weeks. Relapse occurs in approximately 10 percent of cases, especially if use of the antibiotic is discontinued before the primary lesion has healed completely. Donovan bodies may reappear within 7 to 10 days.[35]

Pregnant and lactating adolescents should be treated with an erythromycin regimen and consideration given to adding a parenteral aminoglycoside such as gentamicin. Although no published data exist, azithromycin also may be an appropriate antibiotic during pregnancy. Doxycycline and trimethoprim-sulfamethoxazole are contraindicated during pregnancy.[8]

The treatment regimen for an HIV-positive person is the same as for an HIV-negative person. Treatment can fail in patients with coexisting HIV infection and immunosuppression; in contrast to HIV-negative patients, the mean duration to complete ulcer healing in these patients is significantly longer—25.7 days versus 16.8 days.[22] More intensive and prolonged antibiotic therapy such as an aminoglycoside (e.g., gentamicin 1 mg/kg intravenously every 8 hours) may need to be added.

Merianos and associates[28] reported the possible effectiveness of ceftriaxone for chronic, recurrent granuloma inguinale. Patients in this study had the disease for 1 to 5 years and had received 4 to 10 courses of a single daily intramuscular infection of 1 g of ceftriaxone diluted in 2 mL of 1 percent lidocaine.

PROGNOSIS

Healing is complete in patients who seek treatment early in the course of the disease and who comply with their medication and follow-up regimens.[28,32] One third of patients are reported to recover completely without a recurrence after receiving daily doses of ceftriaxone for 7 to 10 days. Patients with mild recurrences responded to additional ceftriaxone or short courses of oral antibiotics.[28] O'Farrell[32] noted complete healing of lesions in 24 percent of patients who complied with follow-up. Complications of granuloma inguinale include pseudoelephantiasis, urethral stricture, and pelvic abscess, which may require surgery. Vulvectomy is reserved for infections that have not responded to antibiotic treatment or for patients with severe vulvar elephantiasis.[13,35]

The severe, mutilating complications of granuloma inguinale are primarily a result of delayed treatment or poor compliance with medication. In Durban, South Africa, almost half of the male patients had ulcerations for 1 to 6 months before they sought medical care, and 16 percent had ulcerations for 1 to 3 weeks. In contrast, approximately 25 percent of female patients had ulcerations for 1 to 6 months, and 50 percent had ulcerations for 1 to 3 weeks.[28] Delayed medical attention may be related to limited education, ignorance of STIs, absence of suitable medical facilities, or embarrassment in seeking treatment because of extensive genital lesions. Another complication is the acquisition of HIV infection, especially when patients with ulcerations that are left untreated for a prolonged period have sexual contact with an HIV-positive partner.[28,35]

PREVENTION

Sexual partners of persons with the disease should be traced, examined, and treated. Treatment of granuloma inguinale when the nodule first appears is associated with a benign course. Community-based eradication that targets men with granuloma inguinale in endemic areas should be implemented. Programs should be aimed at early suspicion and identification of lesions, access to care, provision of early treatment, and prevention of severe complications. Teaching the importance of personal genital hygiene, such as instruction on simple retraction of the foreskin in men and cleansing the penis with soap and water, also is effective.[32,35] The CDC and the U.S. Public Health Service provide technical instructions on required examinations and standard treatment regimens to panels of physicians and consular officers

evaluating the health of aliens applying for entry into the United States.[6]

CHAPTER 131

Campylobacter jejuni

Ramia Zakhour • Gloria P. Heresi • James R. Murphy

Campylobacter jejuni is a frequent cause of enteritis and less often of extraintestinal infection in humans. Since it first was recognized as a common human pathogen in the 1970s, appreciation of this agent's importance as a cause of disease has increased steadily. *C. jejuni* is one of the most frequent bacterial causes of human enteritis in the United States and is a leading cause of bacterial foodborne diarrheal disease throughout the world.[6,39,273] Immunoreactive complications may develop after infection.[214,228]

Although they are not isolated as frequently as *C. jejuni* and *Campylobacter coli*, other *Campylobacter* spp. are gaining recognition as human pathogens. Currently at least 25 species of *Campylobacter* have been identified.[169] *Campylobacter fetus*, a classic cause of perinatal infection, also is an infrequent cause of bacteremia in immunocompromised hosts. *Campylobacter upsaliensis*, *Campylobacter lari*, *Campylobacter hyointestinalis*, and *Campylobacter concisus* are associated primarily with diarrheal disease. Both normal and immunosuppressed hosts are affected by these species. Other less common *Campylobacter* spp. have been isolated from blood or stool or involved in periodontal disease. The clinical spectrum of these organisms is expanding as the testing for them becomes more widely available.

HISTORY

The pathologic consequences of infection with *Campylobacter* were recognized first in 1909 from studies of abortions in sheep,[174] although it may have been identified earlier, in 1886, when Theodore Escherich described nonculturable spiral-shaped bacteria.[249] A few years later, Smith[259] reported their association with bovine abortion, as well, and gave them the name *Vibrio fetus*. Although never confirmed microbiologically, these organisms are thought to have been *C. fetus* according to current nomenclature.[148] In 1947 the sheep abortion–associated organism *V. fetus* was isolated from a blood culture from a pregnant woman who had an influenza-like illness and delivered a stillborn infant with a necrotic, infarcted placenta.[300] In 1957, King[152,153] hypothesized that *V. fetus*–related organisms could be associated with human enteric disease. In addition to pregnancy, gastrectomy, tooth extraction, heart disease, diabetes, and cirrhosis were predisposing conditions in King's 1957 review of 15 patients with *V. fetus* bacteremia.[153] Butzler and colleagues[35] showed that bacteria similar to *V. fetus* were present in the stools of children with diarrhea. This observation was confirmed rapidly and repeatedly.[23,36,93,255,275] Major differences in biochemical activities, growth characteristics,

and DNA base nucleotide content between true vibrio and *V. fetus* led to the establishment of the new genus *Campylobacter* by Sebald and Vernon in 1967.[298] The genome of a representative *C. jejuni* was published in 2000.[210] Information gleaned from this and comparative analyses of additional isolates have markedly advanced knowledge of these agents.[88,117]

Many reports describing new *Campylobacter* spp. were published in the 1980s and early 1990s. *C. upsaliensis* was reported to be a pathogen in dogs and humans in 1983 and 1985, respectively.[210,238] *C. lari*, a common isolate from healthy seagulls, was found to be a cause of gastrointestinal and extraintestinal disease in humans.[17,274] Originally identified in the intestines of swine with proliferative ileitis, *C. hyointestinalis* was reported first as a human pathogen in a homosexual man with proctitis.[71] The hydrogen-requiring campylobacters *C. concisus*,[295] *C. rectus*,[226] and *Campylobacter curvus*, as well as *Campylobacter showae* and *Campylobacter gracilis*, have been associated with periodontal disease. *Campylobacter sputorum* has been identified in abscesses,[189] as well as in bacteremia[50,119] and gastroenteritis,[169] and *Campylobacter mucosalis* was reported in two children with diarrhea.[75] *Campylobacter ureolyticus*, initially known as *Bacteroides ureolyticus*, was first described associated with genital tract infections and only more recently found to be isolated from stools.[31,78] Once called *Campylobacter*-like organisms, *Helicobacter cinaedi* and *Helicobacter fennelliae* are now classified in the *Helicobacter* genus.[199] These pathogens cause enteritis and proctocolitis in homosexual men and, on occasion, bacteremia.[209,289] Two former *Campylobacter* spp., *Arcobacter butzleri* and *Arcobacter cryaerophilus*, are associated with abortion and enteritis in cattle and pigs, in addition to bacteremia and diarrhea in humans.[151]

THE ORGANISM

Campylobacter is a Greek word meaning "curved rod." Members of this genus are fastidious, non–spore forming gram-negative rods that are curved, S-shaped, or spiral (Fig. 131-1) and may vary in width from 0.2 to 0.9 μm and in length from 0.5 to 5.0 μm.[294] Although most grow at 37°C (98.6°F), *C. jejuni* grows best in cultures maintained at 42°C (107.6°F). Most *Campylobacter* spp. require microaerophilic growth conditions (5% to 10% oxygen). *Campylobacter* spp. usually are motile, with either a single polar flagellum or two flagella, one at each end of the rod. Exceptions include *C. gracilis*, which is nonmotile, and *C. showae*, which has multiple flagella. Campylobacters are oxidase-positive and reduce nitrates but do not ferment or oxidize carbohydrates.[212]

Some species, including *C. sputorum*, *C. concisus*, *C. mucosalis*, *C. curvus*, *C. rectus*, and *C. hyointestinalis*, may require hydrogen for primary isolation and growth. Many media selective for isolation of *Campylobacter* spp. have been developed, but because of species differences in antibiotic resistance patterns, no single formulation allows isolation of all species of clinical importance.[100] For example, *C. jejuni* and *Campylobacter coli* are resistant to cephalothin, whereas *C. fetus* is susceptible. A filtration method with nonselective media may be used to complement direct culture on selective media for the detection of antibiotic-susceptible *Campylobacter* spp. Because of their small size and motility, campylobacters may pass through filters with pores of 0.45 to 0.65 μm, whereas other enteric flora are retained.[7,189]

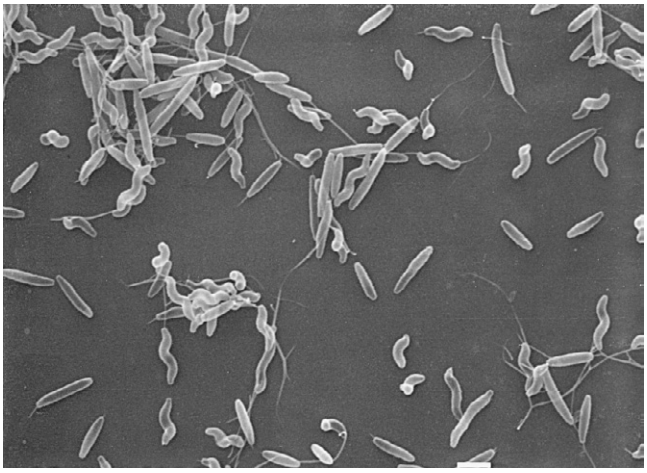

FIGURE 131-1 ■ Scanning electron microscopy of *Campylobacter jejuni* strain 20-01. (From Baqar S, Rice B. *Campylobacter jejuni* enteritis. *Clin Infect Dis* 2001;**33**:901–5.)

Although colonies may appear on plates within 24 to 48 hours, growth of campylobacters from stool may take as long as 72 to 96 hours. Primary isolation from blood may require 2 weeks.[7] Gram stains of young cultures reveal vibrioid forms, and longer incubation may yield spherical or coccoid bodies. *Campylobacter* spp. usually can be distinguished from one another on the basis of biochemical tests and growth characteristics (Table 131-1). Although the significant pathogens *C. jejuni*, *C. coli*, and *C. lari* cannot be discriminated reliably by the use of 16S rDNA data, these sequences provide a substantially improved basis for the identification and differentiation of *Campylobacter* spp.[97] Many investigators have applied molecular techniques to identify enteric campylobacters directly from stool.[293]

C. jejuni belongs to rRNA superfamily VI, a specialized subgroup of gram-negative bacteria that also includes *Arcobacter* and *Helicobacter*. The species *C. jejuni* has two subspecies, *C. jejuni jejuni* and *C. jejuni doylei*. *C. jejuni doylei* can be differentiated from *C. jejuni jejuni* by the failure of *C. jejuni doylei* to grow at 42°C (107.6°F), lack of nitrate reduction, and sensitivity to cephalothin. For brevity, we refer to *C. jejuni jejuni* as *C. jejuni*.

C. jejuni has a circular chromosome of 1.64 million base pairs (30.6% guanosine and cytosine).[208] Marked differences in pathogenic surrogates (i.e., motility, colonization of chicks, invasion, and translocation of cultured cells) are associated with variable chromosomal sequences within different passage sequences for a single isolate, and unique chromosomal sequences are associated with known pathogenic isolates of *C. jejuni*. Genomic analyses demonstrate that substantial differences exist among organisms classified by conventional means and that some of these differences are associated with the capacity to cause disease in humans.[88,117,207] Genomic sequence analyses have yielded a catalog of phase-variable surface

Epidemiology of *Campylobacter jejuni* infections in the United States and other industrialized countries. In: Nachamkin I, Blaser MJ, Tompkins LS, editors. Campylobacter jejuni: *Current Strategy and Future Trends.* Washington [DC]: American Society for Microbiology; 1992, p. 9–19.)

structures (including lipo-oligosaccharide and capsule) that appear to relate to pathogenesis and immunity,[79,208] a lack of classical operon structure, repetitive DNA, and an unexpected capacity to produce polysaccharide.[208] Populations of *C. jejuni* are nonclonal, and interstrain exchange of genetic material occurs.[50]

EPIDEMIOLOGY

Human infection with *C. jejuni* occurs worldwide.[20] *C. jejuni* persists in zoonotic niches (Table 131-2), and most human infections are thought to arise from these reservoirs. Chickens and contaminated water are the main sources of campylobacteriosis in developed countries. The organism is a common commensal of the gastrointestinal tract of cattle, pigs, dogs, cats, and most birds used as human food,[24,250] and transmission from these sources occurs. Fresh-water bathing sites may yield *Campylobacter* organisms that are epidemiologically linked to human infections,[197,245,246] and waterborne outbreaks have been reported.[146] In the United States, *C. jejuni* infection peaks in late summer and early fall (Fig. 131-2). In a study from Philadelphia, June and July were shown to be the 2 months with the highest incidence of disease. Overall increase in temperature and humidity are associated with higher risk for disease. Interestingly, cooler river water was associated with higher disease. Lower water temperature has been associated with longer environmental persistence of *Campylobacter*.[305] Dairy cows in the United

Kingdom have higher concentrations of *Campylobacter* organisms in spring and autumn, but the concentration of *Campylobacter* organisms in beef cattle at slaughter does not change with season; as many as 90 percent of beef cattle may be stool-positive for *Campylobacter*.[265] In subtropical areas, the peak incidence of isolation of *C. jejuni* often is associated with the rainy season. In most tropical climates, rates of isolation are similar year-round. Studies in volunteers show an incubation period of 2 to 4 days after challenges ranging from 800 to 100 million colony-forming units.[19] Fecal shedding of *C. jejuni* by humans may last a median of 2 to 3 weeks, with a range of 3 days to several months.[36,148,203]

The distribution of *C. jejuni* infections within populations is linked to the level of industrialization. In industrialized countries, *C. jejuni* infection is often found in children and adults with enteritis and seldom in healthy individuals.[271] In less industrialized areas, *C. jejuni* is isolated frequently from children, even in the absence of enteritis (Tables 131-3 and 131-4). In industrialized countries, *C. jejuni* has been isolated from between 1 and 13 percent of children with diarrhea, and the prevalence of infection in healthy individuals has been reported to be between 0 and 1.5 percent.[23,35,229,255,273] A 5-year, laboratory-based national surveillance of *Campylobacter* spp. showed an isolation rate of 5.5/100,000 person-years (with *C. jejuni* accounting for 99% of the *Campylobacter* isolates; Fig. 131-3).[277] Population-based isolation rates of *Campylobacter* in the United States range from 28 to 1560/100,000 per year.[275,276] The rate of death attributable to *Campylobacter* is estimated between 100 and 124 per year in the United States.[292,293] The case mortality rate is between 0.10[175] and 0.23 percent.[113] FoodNet published that between 1996 and 2005, *Campylobacter* accounted for 9 percent of 552 deaths caused by bacterial pathogens transmitted through food, with a case fatality rate of 0.1 percent; 46,354 laboratory-confirmed *Campylobacter* infections were reported during that period (38% of all bacterial food-transmitted infections and the most common).[15] A registry-based study demonstrated about fivefold and twofold increases in mortality rates for the first 30 days or first year, respectively, after developing *Campylobacter* infection.[113] A Canadian report showed a 5.1 percent hospitalization rate for *Campylobacter* infections between 2001 and 2004, with highest rates at extremes of age (<1 year and >59 years). Population-based studies in England, the United States, and Sweden showed a bimodal age distribution, with a peak of illness occurring in children younger than 5 years and a second peak at 15 to 29 years of age.[233,275] The highest isolation rate occurs in the first year of life (see Fig. 131-3). Recent reports from the United Kingdom suggest a decrease in incidence of campylobacteriosis in the younger age groups in more recent years versus an increase in the population older than 60 years of age.[92] A male predominance of campylobacteriosis is seen, which has been reproducible in an animal model, suggesting physiologic differences in response to infection between the genders.[268]

In industrialized regions, most sporadic cases occur because of handling, preparation, and consumption of contaminated raw or undercooked poultry or beef.* Raw milk and contaminated water are less frequent sources (see Table 131-2).[121,127,178,278,303] Poor kitchen hygiene plays a role in transmission[56,86]; the risk for acquiring infection is inversely related to the frequency of using

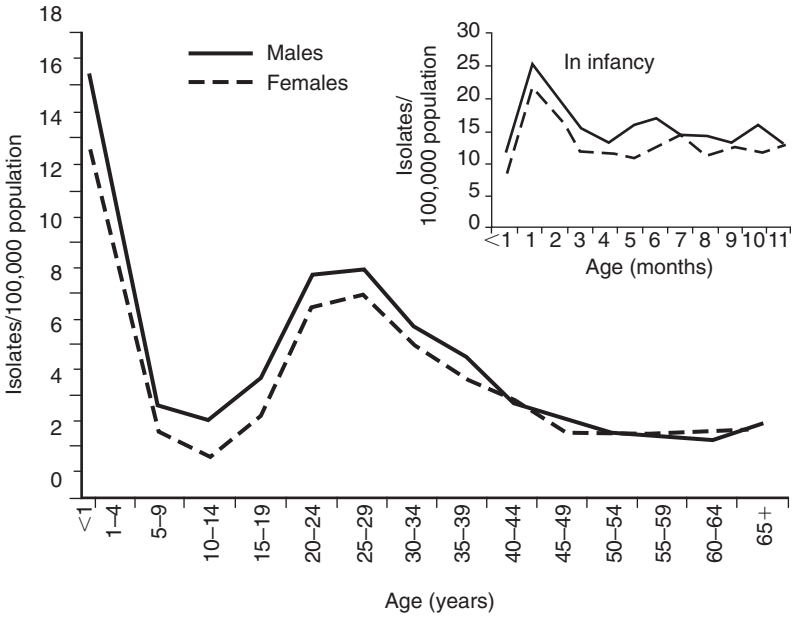

FIGURE 131-3 ■ Annual isolation rates of *Campylobacter* by age and sex, United States, 1982 to 1986. (From Tauxe RV, Hargrett-Bean N, Patton CM, et al. *Campylobacter* isolates in the United States, 1982-1986. *MMWR CDC Surveill Summ* 1988;**37**:1–13.)

soap to clean cutting boards.[275] Barbecues represent a special hazard because they permit easy transfer of bacteria from raw meat to hands and other food and from there to the mouth.[36] Other identified risk factors are eating at restaurants and takeaways.[48,56,86] Sporadic cases of *C. jejuni* infection occur much more frequently than outbreaks. Hospital outbreaks associated with food provided at the hospital kitchen have been reported.[136] Rural setting and higher income have been associated with higher numbers of infections.[18,76]

In less industrialized regions, *Campylobacter* is found in association with childhood diarrhea in 8 to 45 percent of cases, but it is isolated at similar rates from healthy children.[36,47,89] The highest rates of *Campylobacter* isolation are in children younger than 5 years of age.[36] As many as 75 percent of *Campylobacter* infections occurring during the first year of life are asymptomatic.[47]

Usually, a contaminated food or water vehicle transmits *Campylobacter*. However, direct transmission of the agent may occur, usually to individuals with direct exposure to reservoir animals or to those who process contaminated animal products.[31] Person-to-person spread may occur in areas of high contamination, such as where diapered children are present.[211] In addition, intrapartum transmission is documented.[33,299] Asymptomatic mothers may transmit the infection to their newborns.[33]

In developing countries, transmission is multifactorial. Free-roaming poultry, toddlers, unsafe water supply, and lack of adequate disposal of excreta are documented sources.[98] However, proving that *Campylobacter* causes disease in regions where the agent is environmentally pervasive is difficult. Confounders include statistically indistinguishable rates of isolation from diarrhea cases and matched controls (see Table 131-3), and direct evidence that the presence in a household of *Campylobacter* shared between humans and chickens is associated with protection from diarrhea. Improved knowledge of the immune responses that protect from *Campylobacter* infection and disease and knowledge of the components of *Campylobacter* required to cause disease are needed to understand the agent's epidemiology better.

Because of the biochemical inactivity of *Campylobacter* organisms, discriminating species and subspecies by conventional chemotaxonomic methods is problematic. The consequences of this difficulty include ambiguities in epidemiologic investigations and low resolution in studies of mechanisms of virulence and immunity. Effort is being invested in devising genotyping schemes.[59,198,304]

Much needs to be learned about the epidemiology of *Campylobacter* spp. other than *C. jejuni* and *C. coli*, a group of organisms that made up only about 1 percent of *Campylobacter* spp. reported to the Centers for Disease Control and Prevention (CDC) from 1982 to 1986.[275] These organisms are gaining ground as etiologic agents of undiagnosed gastroenteritis. Non-*jejuni*, non-*coli* *Campylobacter* spp. also have been associated with extraintestinal disease, especially bacteremia in patients with comorbidities affecting the immune system.

Age-specific isolation rates of *C. fetus* parallel those of *C. jejuni* and *C. coli;* rates peak in infancy and increase in young adulthood, and *C. fetus* increases substantially in elderly persons. Seasonal distribution patterns of *C. jejuni*, *C. coli*, and *C. fetus* are similar, with peaks occurring in warm months. In a surveillance study, *C. jejuni* and *C. coli* isolates were predominantly from stool, whereas 54 percent of *C. fetus* isolates with a known source were from blood.[275] The epidemiology and antimicrobial susceptibilities of 111 *C. fetus* strains isolated from 103 patients from 1983 to 2000 in Quebec, Canada, were determined.[291] The isolation site was blood in 69 percent of the patients; stool in 20 percent; and other body fluids, including fluid surrounding the aorta, bile, synovial fluid, cerebrospinal fluid, tubo-ovarian abscess, ascites, and pleural fluid, in 11 percent of these patients.[291] *C. fetus*, an important cause of sporadic abortion in cattle and sheep, may be isolated from the intestines and genital tracts of these animals.[212] Contaminated food and water are the suspected sources of infection for sheep, cattle,

and other animals, including goats, pigs, cats, dogs, hamsters, guinea pigs, antelopes, chickens, and turkeys.[81] *C. fetus* bacteremia generally occurs in immunosuppressed hosts (especially elderly men), pregnant women, and neonates.[229,287] Predisposing conditions include alcoholism or cirrhosis, diabetes mellitus, heart disease, malignancy, splenectomy, and corticosteroid or other immunosuppressive therapy.[61,129,231] *C. fetus* is not considered a major cause of gastroenteritis, perhaps because of the failure of this organism to grow in stool specimens evaluated by routine laboratory methods for *C. jejuni* and *C. coli*.[212,275] In addition to raw milk,[306] raw beef liver,[262] and nutritional therapy (i.e., raw fruit, vegetable juice, calves' liver, coffee enemas) are associated with *C. fetus* infection.[38]

First associated with human disease in a homosexual man with proctitis, *C. hyointestinalis* (*hyos*, "hog"; *intestinalis*, "pertaining to the intestines") originally was isolated from the intestines of swine with proliferative ileitis.[71,212] *C. hyointestinalis* also has been isolated from the stool of persons with nonbloody, watery diarrhea.[65]

C. lari is frequently isolated from apparently healthy seagulls, although seagulls do not play a direct role in its epidemiology.[276] Epidemiologically and microbiologically similar to *C. jejuni*, *C. lari* has been reported to cause enteritis in patients with and without a history of animal exposure and bacteremia in two elderly patients with multiple myeloma and permanent pacemakers.[183,191,252,276] A waterborne outbreak of *C. lari*–associated gastroenteritis also has been reported.[27]

C. upsaliensis group is associated with gastroenteritis, breast abscess, spontaneous abortion, and bacteremia in normal hosts, as well as opportunistic infections in immunocompromised persons.[105,107,210] Conditions predisposing to *C. upsaliensis* bacteremia include gallbladder surgery, ectopic pregnancy, kwashiorkor, and acquired immunodeficiency syndrome (AIDS).[210] Young puppies and kittens are potential transmitters of *C. upsaliensis*,[106] and an outbreak in a child care center suggesting direct transmission between humans has been reported.[94,139]

C. concisus has been implicated in gastrointestinal disease. In contrast to *C. jejuni*, disease distribution was year-round rather than higher in certain seasons. Patients most commonly affected were children younger than 1 year of age and elderly people.

PATHOLOGY

Most *C. jejuni* infections are not associated with illness or notable pathologic features. When illness does occur, watery diarrhea, invasive enteritis, or systemic infection may result. The spectrum of pathology reflects this range of manifestations. Acute watery diarrhea may occur in the absence of grossly visible pathologic features. Acute inflammation of the colon and rectum is the hallmark of *C. jejuni* invasive enteritis,[168] although hemorrhagic jejunitis and ileitis may also occur.[68,148,152,257] In patients who have undergone proctoscopy, normal mucosa is found in approximately 50 percent; in the remainder, mucosal edema, congestion, friability, and granularity are seen. The spectrum of histologic changes ranges from minimal edema with acute and chronic inflammatory cells and no vascular congestion, to moderate inflammation and cryptitis, to crypt abscess formation. Acute appendicitis, mesenteric lymphadenitis, and ileocolitis have been reported in patients who have undergone appendectomies while they were infected with *C. jejuni*.[19] *C. jejuni* infection is at low frequency a precursor to immunoreactive complications in which disease results from immunologic effectors generated in response to infection that damages neurons. The demonstration that, after adjustments for comorbidities, *Campylobacter* infection is associated with increased mortality over the course of a 1-year period after infection suggests that as yet unidentified severe late disease occurs.[113] *C. jejuni* is one of a few microbes that have been hypothesized to trigger a common mechanism leading to lymphomas.[104]

PATHOGENESIS

The mechanisms by which *C. jejuni* causes diarrhea, dysentery, and, less frequently, systemic disease are not well understood. Campylobacters have been shown to invade different cell lines. Motility, adherence, and invasion of cells and ability to produce toxins have been associated with capacity to cause disease,* but the pattern of their expression in disease-associated isolates is not uniform. Dogs,[224] rhesus monkeys,[77] rabbits,[264] mice,[77] and hamsters[123] have been evaluated as models of *Campylobacter* enteritis, but none faithfully reproduces the disease seen in humans. A mouse intranasal challenge model[14] has been developed for use in studies of *C. jejuni* invasiveness, and a ferret model[16] has been developed for studies of *C. jejuni*–induced diarrhea. Studies in mice mainly have served as disease models associated with other *Campylobacter* spp.[169] As few as 500 to 800 colony-forming units have been shown to have the potential to cause disease.[135]

Capsular polysaccharides produced by *C. jejuni* have been shown to increase adherence to human intestinal epithelia and provide resistance against some epithelial antimicrobial peptides, including β-defensin and lysozyme. Flagella help overcome peristalsis and allow entry into the mucous layer. Secreted flagellar and nonflagellar proteins are required for adhesion and invasion. Absence of flagellin A (flaA) has been shown to be associated with decreased motility and virulence. Cytolethal distending toxin (CDT) is the best-characterized toxin associated with *Campylobacter*. It comprises three subunits: *cdt*A and *cdt*C play a role in binding to host cells and allowing delivery of *cdt*B, which has a DNAse I–like activity and plays a role in destruction of the host cells. Types IV and VI secretion systems have been described associated with various *Campylobacter* species. *C. fetus* and *C. rectus* have a surface layer that makes them more resistant to lysis and phagocytosis than other *Campylobacter* spp. Survival of *Campylobacter* spp. is facilitated by the ability to form biofilms.

In vitro studies demonstrate a capacity to disrupt tight junctions of intestinal epithelial cell monolayers and preferentially induce proinflammatory cytokine responses,

*References 11, 12, 83, 84, 103, 114, 145, 169, 182, 249, 316.

through activation of nuclear factor κB (NF-κB) and production of interleukin (IL)-18. These capacities and the demonstrated microtubule-dependent eukaryotic cell evasion mechanism[154] may contribute to establishment and maintenance of *C. jejuni* in the gut.[42]

IMMUNITY

The preponderance of evidence of protective acquired immune responses to *C. jejuni* comes from studies of children in developing countries. Such children have more frequent symptomatic infections at younger ages; with increasing age, the rate of symptomatic infection decreases. The number of *C. jejuni* organisms excreted per gram of stool of infected individuals also declines with increasing age,[279] as does the duration of excretion of the organism.[277] These phenomena parallel increasing titers of *Campylobacter*-specific antibodies.* Serum *Campylobacter* IgA and IgM increase within a week of the infection and disappear within 2 to 3 months, whereas IgG levels increase several weeks after infection and last significantly longer.[112] Specific IgA can be isolated from the stools of infected subjects, as well. Additional inferential evidence includes that breast-feeding is associated with reduced frequency of *C. jejuni* diarrhea.[235,288] Adult volunteers who became ill after a first challenge were protected from illness after repeat challenge with an homologous strain[19] and resistance related to the presence of anti-*Campylobacter* antibodies. A Canadian study showed recurrence rate of *C. jejuni* infection within 5 years after an initial infection to be 1.2 percent, suggesting that immunity against *C. jejuni*, at least in developed countries where the environmental load of *Campylobacter* may not be very high, is not persistent or sufficient to protect from subsequent infections.[10] Prolonged, severe, and sometimes recurrent infections occur in immunodeficient patients.[172,176,218] Hypogammaglobulinemic patients have difficulty clearing *Campylobacter* organisms. Patients with late-stage acquired immunodeficiency syndrome (AIDS) are at increased risk for acquiring severe relapsing *Campylobacter* infection; patients with early stages of human immunodeficiency virus (HIV) infection and high CD4 counts are not at risk. Immunity to disease may not protect against asymptomatic colonization. The bacterial components against which the protective immune responses are directed are not known, although several potential immunogenic antigens and virulence factors have been investigated.[196] The sum of this evidence forms the basis for attempts to develop *C. jejuni* vaccines.

Very little information is available on cellular immune responses to *C. jejuni*. Cellular responses may play an important role in facilitating the formation of antibody and in clearing intracellular *C. jejuni* from eukaryotic cells.[135]

A recent in vitro organ culture model system using human gut has shown microcolonies of *C. jejuni* to adhere more frequently to small intestine tissue than to colon tissue, despite similar cytokine responses in the tissues. Significant increase in production of interferon (IFN)-γ and IL-22 was noticed in the presence of *C. jejuni*, as well as IL-23 and to a lesser extent IL-17 production, inferring the presence of an innate and adaptive Th1/Th17 immune response to *C. jejuni*. It was also suggested in mice models that innate immunity and nitric oxide production play an important role in response to *C. jejuni* infection.[271]

Despite the mass of evidence indicating protective roles for immune responses, the *Campylobacter* components against which protective immune responses are targeted are not known. Similarly, attempts to relate classic serotyping schemes, flagellar types, or presence or absence of virulence factors with disease-causing capacity have yielded associations of poor strength. The completion of the genome sequence of *C. jejuni*, NCTC 11168, in 2000[208] enabled studies to be pursued that are beginning to explain the relationships between bacterial components and immune responses. The *Campylobacter* glycome is remarkably plastic,[147] and *Campylobacter* spp. produce a surprising variety of carbohydrates (~8% of the genome is dedicated to the biosynthesis of surface carbohydrates). Furthermore, multiple mechanisms exist for sequence variation for genes encoding the glycome. In a clinical trial, researchers demonstrated that passage of *C. jejuni* in volunteers can be associated with phase variation in lipo-oligosaccharide.[223]

CLINICAL MANIFESTATIONS

C. jejuni produces a spectrum of manifestations, the most common of which is enteritis. Bacteremia, other systemic manifestations, and perinatal infections occur infrequently.

Enteritis

Children with *Campylobacter* enteritis may have unformed stools, watery diarrhea, inflammatory diarrhea, or a combination of these.* Inflammatory diarrhea can be so severe that it is misdiagnosed as inflammatory bowel disease.[255] Inflammatory diarrhea is a more common occurrence in industrialized countries, and secretory watery diarrhea more typically occurs in developing areas. Patients developing diarrhea abroad tend to keep the presentation that is common in their country of origin.[315] Patients with ciprofloxacin-resistant strains have a longer duration of diarrhea than patients infected with sensitive strains,[194] although a recent study from Finland shows opposite results.[72]

Most cases of enteric illness subside within 7 days, although 20 to 30 percent last for 2 weeks and a few (5% to 10%) may persist longer, with a relapsing course lasting for weeks.[148,203] In one third to half of patients, the initial symptoms are periumbilical cramping, intense abdominal pain, malaise, myalgia, and headache. An acute abdomen or appendicitis may be suspected at first[40]

*References 22, 24, 141, 171, 269, 279, 284.

*References 7, 23, 21, 36, 148, 203, 255.

because acute abdominal pain occasionally may be the only initial symptom; pseudoappendicitis or mesenteric adenitis and terminal ileitis can be found.[215] The pain may be mild and intermittent for several weeks, and vomiting is a common occurrence. Secretory diarrhea with 10 or more profuse, watery stools per day may be present. Because this course occurs commonly in younger children, dehydration frequently (10%) is an outcome. Relapse of symptoms may occur.

The symptoms of inflammatory diarrhea are similar to those caused by *Shigella*, invasive *Escherichia coli*, and *Salmonella* and consist of generalized malaise, fever, abdominal cramps, tenesmus, bloody stools, and the presence of fecal leukocytes on light microscopy.[168] Fever without other symptoms may develop and can be associated with febrile seizures.[309] Toxic megacolon with massive bleeding may occur.[101,143,243] In neonates, blood-streaked formed stools or hematochezia may be associated with the isolation of *C. jejuni*.[101,143] The abdomen is tender, especially in the right lower quadrant. Splenomegaly occurs rarely.

C. upsalensis and *C. concisus* are the two most common emerging campylobacters to cause gastroenteritis, although reported cases of gastroenteritis associated with *C. fetus*, *C. hyointestinalis*, *C. insulaenigrae*, *C. lari*, *C. mucosalis*, *C. sputorum*, and *C. ureolyticus* exist.[169] These emerging *Campylobacter* spp. may have an important role in gastroenteritis without an identifiable etiology.

C. upsaliensis was the only organism isolated from 83 patients in a large stool culture survey using a filtration system for *Campylobacter* in Belgium.[96] Ninety-two percent of patients had diarrhea, which was of acute onset. Vomiting (14%) and fever (7%) were uncommon occurrences, and symptoms generally abated in less than a week. Gross or occult blood was identified in 25 percent of cases, and neutrophils were seen on fecal smear in approximately 20 percent. Erythromycin (11 patients) or amoxicillin (2 patients) eradicated the organism, with resolution of symptoms in all 13 patients treated with antibiotics.[96] An Australian study identified *C. upsaliensis* in 19 (0.1%) of 18,516 stool specimens from August 1992 to March 1999 at the Royal Children's Hospital in Melbourne.[139] Infection with *C. upsaliensis* was associated with milder disease than was infection with *C. jejuni;* patients with *C. upsaliensis* infection had significantly less fever, diarrhea, and rectal bleeding.

C. concisus has been associated with gastroenteritis in children. In an older study, *C. concisus* was isolated from 13.2 percent of stools of 174 children with diarrhea versus 9 percent of 958 children without gastrointestinal manifestations.[169] A more recent study from Denmark showed *C. concisus* to be the second most common bacterial isolate from stools of 8302 patients studied, and the annual incidence was reported to be 35/100,000 inhabitants. In this study, healthy controls were not found to have *C. concisus* in their stools, which contradicts previous studies that questioned the true pathologic role of *C. concisus*, especially in children. Four genomospecies of *C. concisus* exist that may have different virulence and clinical manifestations.[160,195]

Six clinical *C. lari* isolates were referred to the national *Campylobacter* reference laboratory at the CDC in 1982 and 1983.[276] Clinical illness associated with these isolates included enteritis in four patients, severe crampy abdominal pain in a 7-year-old girl, and terminal bacteremia in a 71-year-old man with multiple myeloma and chronic renal failure. The ages of the four patients with enteritis were 8 months, 3 years, 22 years, and 39 years. Diarrhea was watery or mucoid, and fever was an unusual occurrence. Potential exposure included consuming chicken, having contact with house pets, drinking untreated surface water, and eating raw oysters. *C. lari* colitis also developed in an HIV-infected woman.[69]

C. hyointestinalis has been isolated from the stool specimens of adult and pediatric patients experiencing nonbloody, watery diarrhea[65] and a rectal culture from a homosexual man with proctitis.[71] Over a 4-year period, 20 strains of *C. curvus* were isolated from two separate and distinct clinical settings, a hospital survey of infectious causes of bloody diarrhea and an outbreak of Brainerd (chronic) diarrhea in northern California.[1]

A study from Ireland was the first to report isolation of *C. ureolyticus* from diarrheal stools; the organism accounted for 23.8 percent of 349 stool samples that were *Campylobacter* positive. Of 8 patients who were followed clinically, only 2 were pediatric patients aged 1 and 6 years. All 8 patients presented with abdominal cramping and had symptoms of more than 5 days' duration. Three of the patients were immunosuppressed (2 diabetic and 1 with HIV-associated lymphoma).[31]

Extraintestinal Infections

Bacteremia with *C. jejuni* occurs much less commonly than enteritis. Bacteremia was recognized first in malnourished children, patients with chronic illness or immunodeficiency, and patients at the extremes of age.[4,102,176,227] Cirrhosis, cancer, immunosuppressive therapy, and HIV infection commonly are underlying conditions in patients with bacteremia.[220] These findings led to the view that *C. jejuni* bacteremia was a disease of the relatively immunocompromised patient. However, most *C. jejuni* blood isolates are from healthy individuals who often have histories of recent gastrointestinal disease.[256] The average incidence of *Campylobacter* bacteremia in England and Wales is 1.5/1000 intestinal *Campylobacter* infections. The CDC reports that only 0.4 percent of *C. jejuni* isolates in the United States are from blood cultures.[275] Most *C. jejuni* strains are susceptible to killing by serum, a finding that perhaps explains the transient nature of the bacteremia and its tendency to resolve without specific therapy. In HIV-infected patients, *Campylobacter* bacteremia occurs more frequently and with increased morbidity and higher mortality rates,[170,220,280] although these numbers have improved after the era of combined antiretroviral therapy. Fatal cases have been reported in the absence of enteric disease.[170] In a Danish study reporting 46 cases of *Campylobacter* bacteremia over a 10-year period, the incidence of bacteremia was estimated at 2.9/1 million person-years. Only one case was reported in a child. Patients with bacteremia tended to be older than patients with isolated enteritis, and enteritis was detected in 59 percent of patients with bacteremia. *C. jejuni* accounted for 37 cases; *C. coli*, *C. fetus*, and *C.*

lari were responsible for the rest. The mortality rate associated with bacteremia was 4 percent. Patients who survived had no recurrence within a 365-day follow-up period. A study from Spain reported an incidence of 4.7/1 million person-years over a 23-year period (71 episodes of bacteremia). Of these events, 31 percent originated extraintestinally and 26 percent were primary infections. Isolates included *C. jejuni* (66%), *C. coli* (19%), and *C. lari* (12%). The mortality rate was 16.4 percent. The recurrence rate was 5 percent. In both studies patients had comorbidities, including major gastrointestinal surgeries, alcoholism, HIV, immunodeficiency, and malignancy.[73] In the largest recent series of *Campylobacter* bacteremia, 183 cases were reported from France in 178 patients in a 5-year period. Only 7 patients were younger than 15 years of age. Fever was the only presenting symptom in 42 percent of cases. *C. fetus* accounted for 57 percent of cases. Other isolated *Campylobacter* spp. included *C. jejuni*, *C. coli*, and *C. lari*.[201]

Bacteremia is one of the most common presentations of uncommon *Campylobacter* species (Table 131-5).

The main reason for the increased recognition of extraintestinal *Campylobacter* infections appears to be the growing application of appropriate microbiologic culture methods. The incidence of *C. jejuni* bacteremia probably remains underestimated. Typically, blood cultures are not performed in individuals with the primary complaint of diarrhea. Rarely,[222] cholecystitis, urinary tract infection,[49] pancreatitis,[85] hepatitis,[155] and meningitis[61,284] can result from *Campylobacter* infection.

C. fetus is the non-*jejuni*, non-*coli Campylobacter* most commonly described to cause disease in humans. It is known to cause perinatal disease but is otherwise rare in healthy children. More commonly it can cause bacteremia in adults with other comorbidities, especially immune suppression. Typically, illness begins with fever, malaise, and headache. Chills and night sweats are prominent, as is weight loss in prolonged illness. Diarrhea, nausea, vomiting, and abdominal pain occur in as many as 38 percent of cases, and hepatosplenomegaly or jaundice develops in two thirds.[102,310] Pulmonary involvement is a rare finding.[25,102]

C. fetus also has a tropism to the vessels. Three patterns of invasive *C. fetus* disease have been described.[231] Clinical manifestations of the first localized infection accompanied by septicemia include meningitis,[29,163] endocarditis,[70] pericarditis,[184] thrombophlebitis,[37] mycotic aneurysm,[231] cellulitis,[37,80] gluteal abscess,[53] septic arthritis,[159] salpingitis,[29] and peritonitis.[272] The second form is transient asymptomatic bacteremia, which may be self-limited.[102,229,232] Prolonged and recurrent bacteremia, with waxing and waning symptoms as spontaneous relapses and remissions occur, is the third pattern of invasive *C. fetus* infection.[25,45,133,233,310]

C. curvus also was reported to be associated with polymicrobial liver and lung abscesses in two patients with cancer. *C. rectus* was reported in a polymicrobial breast abscess in a patient with lymphoma.[1] *C. concisus*, *C. curvus*, *C. gracilis*, *C. lari*, *C. mucosalis*, *C. rectus*, *C. showae*, *C. sputorum*, and *C. ureolyticus* can be isolated from the oral cavity. *C. rectus* and *C. gracilis* are thought to be associated with periodontitis.[169]

The extraintestinal clinical features of "other" *Campylobacter* spp. are presented in Table 131-5.

TABLE 131-5 **Clinical Features Associated with Extraintestinal Infection by "Atypical" *Campylobacter* Species**

Species	Extraintestinal Clinical Features
C. fetus	Bacteremia, sepsis, meningitis, vascular infections, septic abortion
C. upsaliensis	Bacteremia, abscesses, abortion, hemolytic-uremic syndrome
C. lari	Bacteremia
C. hyointestinalis	Bacteremia
C. sputorum	Pulmonary, perianal, groin, knee, and axillary abscesses, bacteremia
C.concisus	Periodontitis, brain abscess[54]
C. curvus	Liver abscess, bronchial abscess, bacteremia
C. gracilis	Periodontitis, brain abscess[54] head and neck infection
C. rectus	Periodontitis, necrotizing soft tissue infections, empyema thoracis,[160] vertebral abscess[54]
C. showae	Intraorbital abscess[54]
C. ureolyticus	Oral and perianal abscesses, soft tissue and bone infections
C. insulaenigrae	Bacteremia
C.hominis	Bacteremia

Perinatal Infections

Occasionally, abortion or stillbirth, premature labor, neonatal sepsis, and meningitis caused by *C. jejuni* have been described, although these manifestations have been more commonly associated with *C. fetus*.[213] *Campylobacter*-associated second-trimester abortion generally is preceded by mild gastroenteritis.[186,253] The placenta may have areas of necrosis, infarction, microabscesses, and inflammation. The most likely route of placental or fetal infection is through the bloodstream, although a case with possible ascending spread has been reported.[57] Maternal blood, placenta, cervix, vaginal, and stool cultures have yielded *C. fetus* in reported perinatal cases.[163,253,308] Infected infants often are premature. Illness in neonates generally is mild or asymptomatic, but symptomatic gastroenteritis and asymptomatic bloody diarrhea caused by *C. jejuni* have been reported in newborn infants.[30,203] Bacteremia and meningitis also may occur.[95,284] Hemorrhagic infarction and necrosis, as well as cystic degeneration of the cerebral cortex, are the cerebral lesions most commonly reported in *Campylobacter* meningitis.[308] The source of the organism usually has been the mother, who may be symptomatic or asymptomatic at the time of delivery.[30,251]

Immunoreactive Complications

An episode of *C. jejuni* infection may be followed by immunoreactive complications such as Guillain-Barré

syndrome (GBS),[110,111,142,179,230] Reiter syndrome,[140,217,221] reactive arthritis,[64,222,241] and erythema nodosum.[9,82,263,264] A preceding *C. jejuni* infection has been documented by serologic methods or stool culture in 12 to 60 percent of patients with GBS.* *C. jejuni* infection is the most common identified causal factor for GBS.[190,228] However, the risk for development of this syndrome after having a *C. jejuni* infection is less than 1 percent.[6] *Campylobacter*-associated GBS is associated with axonal degeneration and poorer outcome than in GBS associated with other causes.[228] During the 2 months after a symptomatic episode of *C. jejuni* infection, the likelihood of GBS is approximately 100 times (30.4/100,000) higher than the risk in the general population (0.3/100,000).[173] In a nested case-control study from 1991 to 2001 using data from the United Kingdom General Practice Research Database, 20 percent of GBS cases were attributable to *Campylobacter*.[270] A case-control study from India showed 27.7 percent of patients with GBS to have evidence of a recent *Campylobacter* infection.[144] A study from Bangladesh showed higher rates of *Campylobacter* infection preceding GBS with positive serology in 57 percent of cases. Patients with *Campylobacter* infection were more likely to have axonal variant, greater disability, and higher mortality; they also had higher antibodies to gangliosides GM_1 and CD1a.[131] GBS syndrome appears to be an age-related risk; one study found no cases in patients younger than 20 years of age, 14/100,000 in patients aged 20 to 59 years, and 248/100,000 infections in those older than 60 years of age.[173] Certain serotypes of *C. jejuni* are associated more frequently with the subsequent development of GBS.[8,157]

Molecular mimicry between G_{M1} ganglioside and *C. jejuni* lipo-oligosaccharide is established as one of the triggers of GBS.[313] A positive correlation of serologic evidence of *C. jejuni* and the presence of antibody to G_{M1} has been described.[99,134] Lipopolysaccharide extracted from *C. jejuni* was found to have core oligosaccharide resembling human ganglioside G_{M1}. Pure motor neuropathy with a tendency for more distal weakness and sparing of the cranial nerves has been associated with *C. jejuni* infection in patients with anti-G_{M1} antibody.[6,283] *Campylobacter* carrying the *cst-II* sialy transferase gene is associated with the development of GBS and Fisher syndrome, and gene polymorphisms may determine which syndrome develops after having a case of *C. jejuni* enteritis.[313] Cases of Miller-Fisher syndrome, a polyneuritis variant characterized by ophthalmoplegia, areflexia, and cerebellar ataxia, as well as Bickerstaff's brainstem encephalitis (Miller-Fisher variant with impaired consciousness), also have been reported in association with *C. jejuni* infection.[128,314] These patients often have antibodies to ganglioside G_{Q1b}.

Reactive arthritis may be associated with *Campylobacter* enteritis, especially in adults with human leukocyte antigen (HLA)-B27.[64,241]

Campylobacter-reactive arthritis may occur in 1 to 5 percent of patients infected.[222] The arthritis starts a few days to several weeks after the episode of diarrhea. Involvement of joints can be monarticular or multiple, as well as migratory, and both large and small joints can be affected. Synovial fluid is sterile, and fever and leukocytosis are absent; the duration ranges from 1 week to several months. The course is self-limited, and the prognosis is good.[108] A study from Oregon including 6379 culture-confirmed *Campylobacter*, *Salmonella*, *Yersinia*, *Shigella*, and *E. coli* O157 infections showed an incidence of 2.1/100,000 of reactive arthritis after *Campylobacter* infection. Women, adults, and patients with more severe illness were found to be at higher risk for developing this complication. Interestingly, no association with HLA-B27 was found.[290]

C. jejuni and more recently other campylobacters have been suggested to be associated with the development of inflammatory bowel disease in children, although Jess and colleagues[138] relate increased rates of *Campylobacter* infections around the first episode of inflammatory bowel disease to a possible detection bias. In one study, *C. concisus* was isolated from 65 percent (35/54) of stools from children with Crohn disease and 12 other samples were positive for other non-*jejuni Campylobacter* (i.e., *rectus*, *gracilis*, *showae*).[169]

It has also been postulated that *Campylobacter* enteritis can be followed by development of functional gastrointestinal disorders in children, including irritable bowel syndrome and dyspepsia.[241]

Severe, persistent, and relapsing *C. jejuni* infections have been reported in patients with immune deficiencies, including congenital and acquired hypogammaglobulinemia and malnutrition.[4,120,176] In patients with AIDS, increased frequency and severity of *C. jejuni* infection have been reported; the severity correlates inversely with the CD4 count.[164,216,218]

DIAGNOSIS

The initial characteristics of *C. jejuni* enteritis are not sufficiently unique to permit the diagnosis to be established on clinical grounds. The differential diagnosis should include *Shigella*, *Salmonella*, invasive *E. coli*, *E. coli* O157:H7, *Yersinia enterocolitica*, *Aeromonas*, *Vibrio parahaemolyticus*, amebiasis, and pseudomembranous colitis caused by *Clostridium difficile*. Fecal leukocytes are found in as many as 75 percent of cases of *Campylobacter* enteritis; gross or occult fecal blood is present in 50 percent.[19,23,168] White blood cell counts usually are normal, although a shift to the left may occur. Mild elevations in alanine aminotransferase, alkaline phosphatase, and the sedimentation rate are observed in as many as 25 percent of patients.

Methods for demonstrating *C. jejuni* include direct microscopy,[204,206] bacteriologic culture, antigen detection by electroimmunoassay (EIA) or enzyme-linked immunosorbent assay (ELISA),[116,242,286] DNA probes,[281] polymerase chain reaction (PCR),[134,161,200,297] and serology.[7] Detection of antigen by EIA is nearly as sensitive and specific as culture. ELISA using recombinant P18 and P39 as antigens has demonstrated 91.9 percent sensitivity and 99 percent specificity.[242] PCR enables some culture-negative *Campylobacter* infections to be diagnosed.[161,162]

*References 5, 110, 111, 122, 149, 179.

Serologic tests appear useful for epidemiologic investigations but are not recommended for routine diagnosis.

C. jejuni can be detected by darkfield and phase-contrast examination of fresh suspensions of stool. The distinguishing characteristic of *Campylobacter* is darting motility. Gram stain of stool showing *Vibrio* forms is said to be useful in making a presumptive diagnosis.[240] Using the direct carbol-fuchsin Gram-stain method, Wang and Murdoch[302] reported 89 percent sensitivity and 99.7 percent specificity when examining stool samples of *Campylobacter*-infected patients. The indirect fluorescent antibody test can be used for identification of *Campylobacter* on smears; however, standardized reagents for this procedure are not available from commercial sources.

Establishing a definitive diagnosis of *Campylobacter* infection requires the demonstration of the organism in stool or in a tissue sample. Unfortunately, not all laboratories culture for *Campylobacter*, despite its frequency, and not all laboratories use the same culture technique.[167] Culture of *Campylobacter* from stool requires special methods and media. It can be accomplished with media that contain antibiotics[66] to which *Campylobacter* organisms are resistant. If culturing is to be done on medium free of antibiotics, diluted stool samples should be passed through a cellulose acetate membrane filter with a pore size of 0.65 μm to reduce the number of other enteric microorganisms.[66] Inoculated plates should be incubated in 5 percent oxygen and 10 percent carbon dioxide at 37° to 42° C (98.6° to 107.6° F). Colony formation may not be grossly visible until 72 hours after plating. Identification of colonies as *C. jejuni/coli* is based on a Gram stain showing characteristic morphology and positive catalase and oxidase reactions. Hydrolysis of hippurate establishes an isolate as meeting the conventional inclusion criteria for *C. jejuni*. Routine media usually are adequate for isolation of *Campylobacter* from normally sterile body fluids and tissues. PCR analysis performed on fixed, routinely processed colon biopsies is an excellent diagnostic method for detecting *Campylobacter* from focal active colitis cases. An advantage of the PCR on tissue is that it can be done retrospectively from the paraffin block.[244]

TREATMENT

Most *C. jejuni* organisms are susceptible to macrolides, aminoglycosides, fluoroquinolones, chloramphenicol, imipenem, and clindamycin and are resistant to cephalosporins, tetracyclines, rifampin, penicillins, trimethoprim, and vancomycin.[254,296] However, the development of resistance to macrolides is starting to emerge, with case reports worldwide.[90] Patterns of antibiotic resistance in *C. jejuni* show regional differences. In the past, quinolones were used as empirical therapy for adult traveler's diarrhea because of their good microbiologic activity against *Campylobacter*, *Shigella*, and *Salmonella* strains.[6,62,239] However, since the late 1980s, *Campylobacter* strains have become increasingly resistant to fluoroquinolones worldwide, except in Australia (Table 131-6). The emergence of resistance has been associated with the use of quinolones such as sarafloxacin, difloxacin, and enrofloxacin in veterinary medicine in Europe and the United States.[66,67,126,257] The association of human infection with fluoroquinolone-resistant *Campylobacter* spp. and consumption of poultry prompted the U.S. Food and Drug Administration (FDA) to withdraw enrofloxacin for use in poultry, effective September 2005.[193] Despite this measure, it will take time for fluoroquinolone-sensitive *Campylobacter* spp. to be reestablished in the environment. A study comparing infection with erythromycin-resistant and erythromycin-susceptible isolates in children did not show any clinical difference in course of disease or presentation. Although fluoroquinolone-resistant *Campylobacter* is generally thought to cause more severe disease, recent studies show opposite results.

Fluoroquinolone resistance in *C. jejuni* appears to be related to mutations in the genes encoding subunits of DNA gyrase.[119] The frequency of erythromycin-resistant *Campylobacter* isolates is low (see Table 131-6).[237] Azithromycin is considered the drug of choice in adults and children.[63,158] Most patients with *C. jejuni* enteritis have mild symptoms and do not require antibiotic therapy. For these patients, oral rehydration and replacement of

electrolytes are sufficient. Patients who may benefit from antibiotic therapy are those with extraintestinal infections, fever, bloody stool, and symptoms lasting longer than a week.[7] Patients with HIV infection or other immunodeficiency syndromes should be treated.[219]

Data on antibiotic treatment are controversial. A meta-analysis on the effects of antibiotic treatment on duration of symptoms caused by *Campylobacter* spp. looked at 11 randomized control trials. It concluded that antibiotic therapy (with erythromycin, ciprofloxacin, or norfloxacin) shortened the duration of intestinal symptoms by less than 2 days, especially if these drugs were given early in the course of disease.[282] In addition, antibiotic therapy shortened the excretion of *Campylobacter* spp. from feces.[282] All immunocompromised and bacteremic patients with *C. jejuni* infections should be treated with an appropriate antibiotic such as gentamicin, imipenem, or both drugs.[7]

Synergistic combination therapy is indicated for patients with meningitis and endocarditis, in which bactericidal activity is critical.[7,181] Patients with *Campylobacter* in their stool who are being treated for an extraintestinal *Campylobacter* infection with gentamicin should be prescribed supplemental oral therapy because gentamicin is ineffective against *Campylobacter* in the gut.[7]

Prolonged antimicrobial therapy and follow-up blood cultures are warranted for patients with *C. fetus* bacteremia because of the relapsing nature of the illness.[104,184] Chloramphenicol should be used with caution in treating *C. fetus* meningitis because clinical outcome and in vitro susceptibility results for this drug have been disappointing.[163,181]

PREVENTION

Tactics for prevention of campylobacteriosis include breast-feeding and avoidance of raw food and food that has been cooked under conditions that permit the survival of bacteria or that has been handled in such a way that bacterial contamination may occur. Risks for foodborne illnesses, including campylobacteriosis transmitted by restaurant-prepared meals, may be reduced by mandating that food-service employees obtain training in food safety (e.g., thorough hand washing with soap and water after handling raw poultry or meat, cooking poultry to 82°C [180°F] or until meat is no longer pink and juices run clear, and separating raw poultry from other foods during preparation).[39]

A 24-month (2002 to 2004), population-based surveillance case-control study by FoodNet in the United States evaluated infants with laboratory-confirmed *Campylobacter* infection and identified risk factors associated with their infection. Identified risk factors include drinking well water, eating fruits and vegetables prepared at home, having a pet with diarrhea in the home, visiting or living on a farm, riding in a shopping cart next to meat or poultry, and traveling outside the United States.[181] Prevention measures should then be targeted at the potential source. An interesting finding is that attendance at a daycare center did not pose an increased risk in this study.

Selected microorganisms may displace *Campylobacter* from its ecologic niches. This finding may prove useful in reducing *Campylobacter* contamination of food animals.[41,166,180,187] Attempts to develop vaccines against *Campylobacteriosis* continue, but no product is in advanced development yet.

CHAPTER 132

TULAREMIA

Gordon E. Schutze

Tularemia is an acute febrile illness caused by *Francisella tularensis*. Although it is primarily a disease of animals, humans also are highly susceptible hosts.

HISTORY

McCoy[101] published the first documented evidence of tularemia in 1911 when he described a plaguelike disease in ground squirrels *(Citellus beecheyi)* that occurred in Tulare County, California. Within 2 years, McCoy and Chapin[102] isolated and characterized the organism *Bacterium tularense* from naturally infected ground squirrels. They also detailed the pathologic process produced in ground squirrels, defined the susceptibility of other animal species to *B. tularense*, and identified fleas as vectors for the plaguelike disease in 1912.

The first description of tularemia in humans may be that by Homma Soken, a court physician in eastern Japan.[122] In 1837, he described an illness as "hare meat

poisoning." Nearly a century later, Vail[148] and Wherry and Lamb[155] independently reported the first etiologically proved case of tularemia in humans in 1914. Thereafter, knowledge of the organism, susceptible hosts, modes of transmission, and clinical manifestations of disease was acquired rapidly, and retrospective information was assessed in light of this new information. Much of the current understanding of the disease in humans originated from the work of Edward Francis,[51,52] a U.S. Public Health Service surgeon. Intrigued by the new diseases, which were called "deer fly fever" by Pearse[114] in 1911 and "plaguelike disease" by McCoy, Francis relocated to Utah in 1919 and established his laboratory in an unused coal shed.[52-55] Soon thereafter, he recognized the singular cause of these two diseases and renamed them "tularemia" because of isolation of *B. tularense* from blood.[122] He isolated the organism from humans and jackrabbits[51] and demonstrated transmission of the organism by the deer fly.[53]

For a more complete historical review, the reader is referred to the classic paper by Dr. Edward Francis,[52] "A Summary of the Present Knowledge of Tularemia." Almost 9 decades later, this article is accurate and contains most of the knowledge essential for understanding tularemia.

ETIOLOGY

The causative agent of tularemia is *F. tularensis*, named in honor of Dr. Edward Francis. *F. tularensis* is a small (0.2 to 1.0 × 1 to 3 μm), nonmotile, non–spore-forming, pleomorphic gram-negative coccobacillus. It is a strict anaerobe that infects as a facultative intracellular bacterium.[73]

Hesselbrock and Foshay[66] described the morphology as resembling that of the pleuropneumonia group of organisms; the usual coccoid form is a spheroidal cystic structure with a delicate, transparent cell wall. Electron-microscopic studies confirmed the presence of a delicate, almost transparent cell wall, as well as the presence of pili on the surface of the organism.

The outstanding growth characteristic of these fastidious organisms is their requirement for cysteine or sulfhydryl compounds in amounts exceeding those usually present in nutrient media.[44] Although *F. tularensis* grows best on cysteine-glucose-blood agar and on coagulated egg yolk medium and less well in thioglycolate broth, it can be isolated in routine cultures and on enriched chocolate agar.[90,105] Hornick[70] suggested that the addition of cycloheximide and penicillin facilitates isolation of the organism from the respiratory tract or skin ulcers. In a study by Johansson and colleagues,[79] an Amies agar medium with charcoal and a Thayer-Martin medium with antibiotics were equal in preserving bacterial viability for 1 week in contrast to saline or Stuart medium.

F. tularensis is killed readily by heat. Exposure to a temperature of 56°C (132.8°F) for 10 minutes is sufficient for killing. The organisms are not destroyed by freezing and may remain viable in frozen animal carcasses for as long as 3 years. However, adequate cooking renders the meat of game birds and animals harmless. Treatment with tricresol solution (1%) for 2 minutes also kills organisms in tissue; organisms from cultures are killed in 24 hours by 0.1 percent formalin.

Despite serologic homogeneity, four distinct subspecies of tularemia have been identified thus far. *F. tularensis* subsp. *tularensis* (type A) accounts for approximately 90 percent of organisms isolated in North America and has been seen in Europe as well.[61] The less virulent strain *F. tularensis* subsp. *holarctica* (type B) is found primarily in Europe and Asia. These two strains have been found to coexist in the same ecosystem.[98] *F. tularensis* subsp. *mediasiatica* has been isolated primarily in central Asian republics of the former Soviet Union,[112] whereas the subsp. *novicida*, which is isolated rarely, can be found worldwide. Through the use of molecular typing techniques, type A isolates can be divided into two distinct clades, A1 and A2.[133] These clades have been further subdivided (A1a, A1b, A2a, and A2b) based on data from pulsed-field gel electrophoresis and global single-nucleotide polymorphism analysis.[86,89,113] No differences have been noted between infections caused by A2a and A2b; therefore, only three type A genotypes (A1a, A1b, and A2) appear to be clinically important. A1 isolates are mainly found in the eastern United States, and A2 strains occur in the western United States. Infections with A1b have significantly higher mortality rates than do infections from A1a, A2, or B.[89] *F. tularensis* is able to survive and replicate within macrophages in part because of two proteins (VgrG and Ig1I) secreted by the *Francisella* pathogenicity island (FPI).[8] This ability to survive and replicate within the macrophage has been correlated with the organism's high level of virulence. In addition, the organism has been demonstrated to be able to invade human erythrocytes, which may serve to shield the pathogen from antimicrobials.[71] *F. tularensis* does not produce any exotoxin, but pharmacologic tests indicate that the organism contains a lipopolysaccharide (LPS) similar to that of gram-negative bacilli. Unlike LPS of other gram-negative enteric organisms, the LPS of *F. tularensis* is 1000-fold less potent and does not activate macrophages or endothelial cells to release proinflammatory cytokines through Toll-like receptors.[3,123,142,152] The O-antigens of the major subspecies *F. tularensis* that are pathogenic to humans are identical in their carbohydrate content and structure, a finding implying that the differences in virulence among subspecies probably is not the result of the O-antigen.[121,144,151,153]

An electron-dense surface material resembling a capsule has been demonstrated with electron microscopy. This capsule-like complex is not always visible, suggesting it may be upregulated under specific conditions.[7,20]

EPIDEMIOLOGY

Tularemia has been reported throughout the United States, in East Asia, and in Europe.[51,69,99,108-110,137] *F. tularensis* has been found in Canada and Mexico but has not been reported in South America or Africa. Within the United States, the disease most commonly occurs in the south central region. From 1990 to 2000, three states

(i.e., Arkansas, Missouri, and Oklahoma) accounted for approximately half of all reported cases.[17]

In the United States, the incidence of tularemia has been recorded since 1927. From 1990 to 2004, the incidence of tularemia was 0 to 0.06 cases/100,000 persons.[17,19] Recent data from a highly endemic region found an average annual incidence of 0.4 cases/100,000.[18] The number of human cases declined steadily from 1939 (2291 cases[76]) until 1975 (129 cases). Since then, the number of reported cases of tularemia has remained consistent, with a range between 90 and 310 cases annually.[19] This range probably is a gross underestimate of the actual incidence. In 1968, in a serologic survey of 1936 subjects in California, approximately 1 percent of this population had antibody against *F. tularensis*.[42] Using skin test antigens, Casper and Phillip[16] showed that 6.6 percent of 365 persons in eastern Montana had evidence of previous infection with *F. tularensis*. Of the persons in whom skin test results were positive, 80 percent had no previous history of the disease, a finding indicating a high number of subclinical or self-limited infections. The mortality rate for tularemia is 0 to 4 cases per year.[19]

Persons especially at risk are hunters, trappers, meat processors, muskrat farmers,[157] cooks, lawn mowers, and brush cutters,[47] sheep herders and shearers,[77] and laboratory workers.[128,149] The incidence of tularemia among American Indians/Native Alaskans (0.5/100,000) is significantly higher than that in whites (0.04) and African Americans (<.01). In all age groups, boys and men have a higher incidence of tularemia than girls and women.[17] During 1990 to 2000, the average annual incidence of tularemia ranged from 0.06 to 0.1/100,000 in boys (0.03 to 0.06 in girls) 0 to 14 years of age, and the highest incidence occurred in boys aged 5 to 9 years (0.1 to 0.06 for girls). In comparison, adults older than 75 years of age have an incidence of tularemia higher than that of children.[17] Children acquire tularemia by the same routes as adults—vector bites, animal bites, and ingestion of infected, inadequately cooked meat.

Tularemia occurs year-round. However, peaks occur in the summer and winter months, depending on the region. May through August accounted for 70 percent of all cases of tularemia onset during 1990 to 2000.[17] Tularemia occurs more commonly in the central and southern states during the summer months, when ticks are more prevalent. The incidence in the northern and eastern states peaks in the winter months during the hunting season.

The most common sources of human infection are contact with infected animals or their carcasses and bites by ticks or tabanid flies (deer flies). Less commonly, people acquire the disease from the bite of a diseased animal or one in which the mouth has been contaminated by the ingestion of a diseased animal. Numerous outbreaks of human tularemia have occurred by water transmission,[11,21,54,78,83] in water contaminated by voles, beavers, lemmings, and muskrats. Infection also may occur by aerosolization of the organisms, especially in laboratory workers,[84,149] lawn mowers and brush cutters,[47] farm workers (inhalation of dust and threshing material contaminated by voles and other rodents)[34,69] and cleaning infected animals.[65] Person-to-person transmission has not been documented.

Hopla,[69] in describing the ecology of tularemia, states that "rarely does one encounter a zoonotic disease of such complexity." Indeed, to understand the development of epizootics and transmission to humans, one must consider the role of numerous vertebrates (i.e., humans and other animals, both wild and domestic) and many invertebrates.

Approximately 100 species of wild mammals, 9 species of domestic animals, 25 species of birds, and several species of fish and amphibians have been found to be infected naturally,[111] but probably fewer than a dozen species of mammals are important in the transmission of *F. tularensis*.[69] Lagomorphs (rabbits and hares) and some rodents (muskrats, voles) are highly susceptible to *F. tularensis;* sheep and domestic rabbits are susceptible but have low sensitivity to the organism; and cats, cattle, dogs, and horses are virtually insusceptible to infection. Vertebrate animals are called *reservoirs*, but they rarely are true reservoirs because most of them become sick and either die or recover, with elimination of the organism. The varying hare (snowshoe rabbit) is less susceptible to *F. tularensis* and may serve as a reservoir because of its high natural resistance and carrier state.[50] Protozoa, which serve as reservoirs for many other intracellular pathogens, may do the same for *F. tularensis*.[1]

Many invertebrates can be infected experimentally by *F. tularensis*, but relatively few are infected naturally. In 1924, ticks were first described as vectors for *F. tularensis* infection in guinea pigs. However, the role of ticks in the spread of the human disease was not recognized until 1949, when Washburn and Tuohy[154] reported that 56 percent (391/704) of tularemia cases in Arkansas were associated with exposure to ticks. To date, ticks remain the most common vectors for *F. tularensis* in the United States and can serve as reservoirs because the organism can be transmitted from generation to generation by transovarian passage.[69]

At least 13 species of ticks have been found to be infected naturally by *F. tularensis*.[69] The species involved in transmission to humans are *Dermacentor andersoni* (wood tick), *Dermacentor variabilis* (dog tick), and *Amblyomma americanum* (Lone Star tick). A fourth tick, *Haemaphysalis leporispalustris* (rabbit tick), is important in the epidemiology of tularemia. Although this tick does not transmit tularemia directly to humans, it perpetuates the cycle of infection by acting as the sylvatic vector between rabbits.[64]

When the tick feeds on an infected animal, the organisms penetrate the gut into the hemolymph and are disseminated throughout the body, including the salivary glands. The tick then transmits the organisms by injecting them, along with saliva, when it feeds on another animal. In addition, transmission by tick fecal contamination also is likely. Ticks, biting flies (i.e., deer flies), and fleas probably are responsible for the continuing endemic disease in susceptible animals and for epizootic disease. Infrequently, mosquitoes and mites may transport *F. tularensis* mechanically from animal to animal or from animal to human.[69] Humans act as terminal hosts of *F. tularensis*

because they do not transmit it to other humans or to other mammals.

A few cases of tularemia acquired by cat bite have been reported.[5,15,154,158] Because cats rarely are infected by *F. tularensis*, such transmission probably is the result of mechanical transmission from the contaminated teeth or claws of a cat that has come into contact with or has fed on an infected animal. Cat bites may be an important source of disease in children.

Ecogenetic analysis of *F. tularensis* in North America shows that the subspecies have specific geographic distributions across the continent.[46,133] *F. tularensis* subsp. *holartica* was found along the northwestern coast and along the tributaries of the Mississippi River. In contrast, the subspecies *tularensis* spanned the region from the east coast to Arkansas, Oklahoma, Texas, and Louisiana in the south; South Dakota in the north; and the Sierra Nevada in the west. Genetic analysis of the subspecies *tularnsis* in this vast region revealed that type A1 is found primarily in the eastern United States, whereas most type A2 clusters to the West.[86,89,133] This spatial separation of subspecies *tularensis* clades A1 and A2 coincides with the distribution of vectors *A. americanum* and *D. variabilis* in the East and *D. andersoni* and *Chrysops discalis* (deer fly) in the West. The spatial clustering of A1 and A2 also coincides with the distribution of an important host, cottontail rabbits, *Sylvilagus floridanus* and *Sylvilagus nuttallii*, respectively.[46]

PATHOGENESIS

Bacterial and Host Interactions

Much of the knowledge regarding interactions between *F. tularensis* and the host was derived from experimental studies using live attenuated strains. During World War II, live attenuated strains of *F. tularensis* were developed in the Soviet Union in an effort to produce a vaccine.[119,146] In 1956, a mixture of attenuated strains of *F. tularensis* was transferred from the Soviet Union to the United States. From this mixture, a strain of suitable virulence was selected, tested for safety and efficacy, and designated *F. tularensis* live vaccine strain (LVS).[36,38,75] This strain has been used extensively in experimental studies on the development of immunity in humans.

Capsulated *F. tularensis* organisms are thought to be opsonized by human macrophages and dendritic cells through the activation of complement, especially C3, and binding to the complement receptor 3 (CD11b/CD18).[10] The interaction of complement-coated *Francisella* with the macrophage membrane initiates an actin-dependent process then engulfs the bacterium into a unique asymmetric spacious pseudopod loop that forms the phagosome.[24,145] The organism is able to survive and replicate within macrophages in part because of two proteins (VgrG and Ig1I) that are secreted by the FPI.[8] The phagosomes are surrounded by a dense fibrillar coating that begins to disintegrate approximately 3 to 4 hours after infection, a process that allows bacteria free access to the cytoplasm.[23] Approximately 24 hours after infection, replication of cytosolic *Francisella* induces apoptosis that leads to cell death and release of bacteria. Tularemia is followed by effective immunospecific protection of the host; reinfection has been documented.[14] Studies in which the infecting bacteria were suppressed by the use of a bacteriostatic agent such as tetracycline showed that protective immunity seems to be activated approximately 2 weeks after onset of the disease. When tetracycline treatment was initiated on the day of onset of tularemia and was given for 10 days, early relapses were common occurrences. When tetracycline treatment was administered for 14 days, relapses occurred less frequently, thus indicating that protective immunity had begun to arise.[125] Innate immunity involving interferon (IFN)-γ, tumor necrosis factor (TNF) and interleukin (IL)-12 and cells that produce these cytokines (i.e., natural killer cells, neutrophils, and macrophages) are thought to help control the initial phase of primary infection by curtailing the replication of *F. tularensis*.[25] Approximately 2 to 3 weeks after infection, *F. tularensis* elicits both humoral and cell-mediated immune responses. Both responses reach maximal levels during the second week after infection.[22] Because *F. tularensis* is described as a facultative intracellular parasite, the general consensus is that long-term control and clearance ultimately depend on cell-mediated immunity, just as in infections with *Listeria monocytogenes* and *Mycobacterium tuberculosis*.[87,136,159] This finding was confirmed by several trials showing that vaccination with killed tularemia preparations, despite inducing agglutinating serum antibodies, provided poor protection.[14,75,124] Numerous studies showed that passive transfer of mononuclear leukocytes from infected animals to noninfected animals conferred resistance when the nonimmunized animals were challenged with a virulent strain.[129] Ultimately, the presence of tularemia-specific $CD4^+$ and $CD8^+$ T lymphocytes is responsible for clearance of the bacteria.[29,31,40,156] Infection with LVS disrupts the production of proinflammatory cytokines from human macrophages and endothelial cells.[49,141] This event is consistent with the lack of increase in proinflammatory cytokines, with the exception of a slight increase in IFN-γ during the early phase of the infection, in humans with ulceroglandular disease.

The importance of the humoral immune response in tularemia has only recently been considered important.[87] Although the presence of immunoglobulin A (IgA) antibodies in nasal secretions correlates with resistance to infection by aerosolized organisms, earlier work by Bellanti and associates[9] showed that humoral immunity plays a an important role, especially in pulmonary tularemia. Specific antibodies probably are involved initially in delaying the infection, thereby allowing time for the induction of cytokine production and specific T-cell–mediated immunity. This suggestion is consistent with the observation that although neutrophils have only a minor role in resistance to infection, mice depleted of $CD4^+$ T cells or $CD8^+$ T cells, or both, remained capable of controlling and partly resolving a primary sublethal *F. tularensis* infection.[29] Antibodies may function as opsonins for macrophages and neutrophils, but the level of antitularemia antibody does not correlate with protection.[140] Elkins and associates[39] showed that mice deficient in B cells do not succumb to sublethal doses of tularemia

during a primary infection. However, in secondary infection, the presence of cytokines from B cells modulates the response of neutrophils against tularemia-infected hepatocytes and prevents the uncontrolled degranulation of neutrophils that may lead to severe tissue damage and poor clinical outcome.[13,28,33]

The role of neutrophils in the control of *Francisella* infection is thought to be minor but necessary. McCaffrey and Allen[100] showed that neutrophils, like macrophages and dendritic cells, rapidly opsonize *Francisella* but are prevented from mounting the respiratory burst to kill the organism. The organisms then escape to the cytosol of the neutrophils and replicate. However, studies in which neutrophils were depleted from mice showed that mice given a sublethal dose of the LVS or mice chronically infected with LVS became susceptible to infection and died.[129] Although the mechanism of action of neutrophils in these cases is unclear, it may involve direct lysis of LVS-infected hepatocytes.[28]

Persistence of immunity to *F. tularensis* depends on the T-cell response to a variety of antigens; this response may not be noted for as long as 2 weeks after exposure. Poquet and associates[120] showed that virulent strains of *F. tularensis* produce high levels of phosphoantigens that cause a proliferation in γ/δ T cells to a greater extent than does exposure to the LVS. The reduced number of this T-cell subtype in vaccinated individuals could explain the lack of complete protection seen in vaccinated laboratory workers. As with membrane proteins stimulating an α/β T-cell response, heat shock protein chaperones such as DnaK and Cpn60 also create a nonimmunodominant proliferation of T cells in immunized individuals.[43] Denaturation of the protein or carbohydrate of a macromolecular antigen of *F. tularensis* has shown that T-cell reactivity is associated with only protein determinants, whereas human immune serum reacts mostly with carbohydrate determinants of the organism.[2,37,144]

Invasion and Disease Production

A single *F. tularensis* organism of a virulent strain can produce fatal infection in susceptible animals such as mice, guinea pigs, and hamsters.[160] As few as 10 organisms of a virulent strain injected intradermally or 25 organisms given by aerosol may produce systemic disease in human volunteers.[75] The organism may gain access to the human body through the skin, conjunctiva, oropharynx, respiratory tract, or gastrointestinal tract. It spreads by the lymphatics or hematogenously, and bacteremia usually develops during the first week of infection (3 to 12 days).[84] Infection commonly involves the skin, regional lymph nodes, liver, spleen, and lungs. Rarely, the gastrointestinal tract and the central nervous system also are involved.

Histopathologic examination of mammals experimentally infected with *F. tularensis* indicates that the organism disseminates and causes cellular changes in a manner typical of intracellular parasites. After the organism is introduced into a susceptible host, multiplication occurs locally, with early spread to regional lymph nodes occurring within 48 to 96 hours.[38,48] The developing cutaneous ulcer or soft tissue focus goes through a series of changes, in which polymorphonuclear leukocytes are replaced by macrophages. In time, necrosis, epithelioid cell infiltrates, giant-cell formation, and true granulomata may develop.[62,103,127] Organisms are difficult to demonstrate in tissue but occasionally are found at the periphery of lesions. In addition to the development of classic necrotic and granulomatous lesions, degeneration of the parenchyma in the liver and spleen may occur, as may marked hyperplasia of the reticuloendothelial system. These granulomata can organize to form microabscesses and abscesses. The pace of the illness depends on the virulence of the strain, as well as the inoculum size, portal of entry, and immune status of the host.[68] When organisms enter the blood circulation, typical endotoxemia may ensue, sometimes in association with acute rhabdomyolysis.[82]

Autopsies of fatal cases of tularemia in humans have confirmed the findings in experimental animals.[59,94,116] Lymph nodes from patients with nonfatal disease have shown follicular hyperplasia with conglomerates of macrophages and caseating granulomata.[87,94,96,133] These findings are similar to those seen in miliary tuberculosis. In fact, tularemia and tuberculosis may be histopathologically distinguishable only because of the difference in timing of the development of tissue changes,[88] a difference related to the rapid replication of *F. tularensis*.

CLINICAL MANIFESTATIONS

Regardless of the portal of entry, the mode of onset of tularemia and the general features of the disease are the same. The usual incubation period of tularemia is 3 to 4 days, with a range of 1 to 21 days. The onset of symptoms is abrupt. Symptoms include fever, with a temperature usually higher than 39.4°C (103°F), chills, headache, myalgia, anorexia, vomiting, and occasionally photophobia. Fever may be continuous or biphasic, with an intermittent period of defervescence. In untreated patients, fever may persist for longer than 3 weeks. Physical findings usually include lymphadenopathy, hepatosplenomegaly, pharyngitis, and skin lesions. Temperature–pulse dissociation has been described in as many as 42 percent of cases.[45,56] A variety of skin rashes (e.g., maculopapular, vesicular, and pustular rashes; erythema nodosum,[117] and erythema multiforme) may appear during the second week of illness and can last for a few days to several weeks.[6,84,138]

Laboratory studies, including a complete blood count, erythrocyte sedimentation rate, and urinalysis, usually are not helpful in diagnosing tularemia. Sterile pyuria has been reported in patients with tularemia, 22 percent in one study[45] and 32 percent in another.[115] Sterile pyuria combined with a history of fever, dysuria, or low back pain led to an erroneous diagnosis of urinary tract infection in 11 percent of the patients reported by Evans and associates.[45] Increased liver function test values with jaundice and atypical lymphocytosis also have been reported.[57,60] The six clinical syndromes of tularemia can be classified by the portal of entry: ulceroglandular, glandular, oculoglandular, typhoidal, oropharyngeal, and pneumonic.

Ulceroglandular Tularemia

Ulceroglandular tularemia, the most common form of the disease, accounts for more than 75 percent of all cases (in adults and children).[93] The organism gains access through the skin. Approximately 2 days after the onset of general symptoms, the patient reports tender, swollen lymph nodes, most commonly in the axillary or inguinal areas. Within 24 hours, the portal of entry may become evident when a painful swollen papule develops distal to the regional node. This papule ruptures and leaves a punched-out ulcer with raised edges. The ulcer is indolent and, in untreated cases, may persist for longer than a month. The skin over the involved nodes may be inflamed. In untreated cases, approximately 50 percent of the lymph nodes suppurate and drain. In other cases, the nodes remain firm, enlarged, and tender for several months. Mild, generalized lymphadenopathy and enlargement of the liver and spleen may be present.

Glandular Tularemia

The glandular form of tularemia accounts for 15 percent of all cases.[93] Glandular tularemia is almost identical to the ulceroglandular form, except that the portal of entry cannot be identified.[26] The consensus is that the portal is an insignificant break in the skin. Isolated cases of cervical lymphadenopathy have been related causally to *F. tularensis* infection.

Oropharyngeal Tularemia

The oropharyngeal form, which accounts for fewer than 5 percent of all tularemia cases,[93] resembles the ulceroglandular form. The infection is introduced into the oropharyngeal mucosa through infected, inadequately cooked meat. The organisms enter through abrasions, or aerosolization may occur during chewing. Local involvement consists of acute tonsillitis with cervical adenitis.[12] The tonsils may be covered by an exudate or membrane that extends in all directions and may resemble a diphtheritic membrane. Complaints of sore throat usually are out of proportion to the visible pathologic features, but ulcers sometimes are present. The cervical lymph nodes may suppurate. Infrequently, *F. tularensis* invades the lower portions of the gastrointestinal tract, in which case vomiting, diarrhea, and abdominal pain are prominent symptoms. Awareness of the ability of *F. tularensis* to cause oropharyngeal involvement is important for physicians caring for children.[72,85,92]

Oculoglandular Tularemia

In oculoglandular tularemia, which accounts for approximately 1 percent of all cases,[93] the portal of entry is the conjunctival sac, which may become inoculated by rubbing with contaminated fingers, having contact with infected water, splashing of infected liquids, or inhaling infected aerosols. The eyelids may become edematous and the conjunctivae inflamed and painful. Numerous small, sharply defined, yellowish nodules and ulcers may be present on the palpebral conjunctivae.[132] In some cases, corneal ulceration occurs. As seen in cat-scratch disease, the Parinaud complex of unilateral preauricular lymph node involvement and conjunctivitis can result.[132,134] The regional lymph nodes, the preauricular nodes, and the submaxillary and cervical nodes are swollen, tender, and painful.[117] In severe cases, the axillary nodes may be involved.[52]

Typhoidal Tularemia

Typhoidal tularemia is manifested as fever of unknown cause. The symptoms are those of acute septicemia, with no localized skin lesions and often without lymphadenopathy. Patients are seriously ill, and shock may develop. The symptoms and signs of typhoidal tularemia are toxemia, continuous fever, myalgia, and severe headache. Patients may be delirious and may exhibit meningismus. Patients often complain of having severe pharyngeal pain, but pharyngeal lesions may not be evident. Diarrhea occurs in this form of tularemia in both adults and children. Sometimes, a dry cough and retrosternal pain are present. Pleuropulmonary involvement is a common finding in adults with typhoidal tularemia.[35] In children, typhoidal tularemia can be the result of ingestion of the causative agent, and necrotic lesions may be present throughout the bowel.[35] Inhalation of aerosolized organisms is a more common mode of acquisition in adults (e.g., laboratory workers and farmers).

Pneumonic Tularemia

The pneumonic form of the disease occurs most commonly in laboratory workers and is the most severe and lethal form.[75] Pneumonic tularemia may be acquired by the aerogenic route,[34,47,143] or pulmonary disease may be associated with other forms of tularemia, particularly the typhoidal type. Dienst[35] and Miller and Bates[105] published outstanding descriptions of pleuropulmonary tularemia. Miller and Bates stressed that the symptoms and signs of pleuropulmonary tularemia are nonspecific and vary with the location and degree of pulmonary involvement. The variable radiographic features may be confused with those of tuberculosis, mycotic infection, common bacterial pneumonia, lymphoma, or carcinoma of the lung. In the series of 29 patients by Miller and Bates,[105] pleural effusion developed in 6 patients. Pleural effusions have been found to contain more than 3 g of protein/100 mL and more than 1000 white blood cells/mm^3, with a lymphocytic predominance.[58] Because of the necrotizing nature of the pathologic process, the lung may heal with residual fibrosis or calcification. In other instances, the disease is so fulminant that death occurs before the pathologic features can progress fully.

Additional Clinical Manifestations

All large series of reported cases have included patients with subcutaneous nodules resembling those seen in sporotrichosis. The nodules usually are distributed on the anterior or posterior surface of the arm and may extend from the primary lesion to the regional lymph nodes. Initially, these nodules are firm and movable, but later

they become fixed to the skin and may suppurate. They vary in size from less than a centimeter to more than several centimeters, if they become confluent. As many as 30 single nodules may be present. Other unusual manifestations of tularemia include pericarditis, appendicitis, peritonitis, liver abscess, cerebellitis with ataxia, meningitis, encephalitis, osteomyelitis, rhabdomyolysis, and venous thrombosis.[30,67]

The incidence of these forms in children is somewhat different from that in adults. Although the pneumonic form previously was thought to be relatively rare in children,[92] more recent studies on the changing epidemiology and clinical manifestations of this disease showed that the occurrence of pneumonic tularemia is not uncommon.[74] In a 1985 study by Jacobs and associates,[74] 14 percent of tularemia cases in children were the pneumonic form. This percentage contrasts with the absence of pulmonary involvement in a series of 48 cases of tularemia in children reported by Levy and associates[92] in 1950. The distribution of these forms of tularemia also varies with the geographic location. In a report of 67 children with tularemia in Finland, 79 percent of the cases were of the ulceroglandular form and 8 percent were glandular.[147] This distribution is significantly different from that in the United States. In the study by Jacobs and associates,[74] who reported on 28 cases of tularemia in children, 45 percent were ulceroglandular, and 25 percent were glandular. More recently from the same region, of the 30 cases described, 57 percent were ulceroglandular disease.[131] The authors of the Finnish study attributed the higher proportion of the ulceroglandular form in their study to heightened awareness of the disease and early diagnosis. In addition, the differences also could be explained by the different strains of *F. tularensis* and different vectors in the two regions.

F. tularensis also can occur in the setting of an immunocompromised host. The pneumonic form of tularemia was reported in a patient with chronic granulomatous disease requiring lobectomy.[97] Pneumonic tularemia also was seen in a patient who previously had undergone peripheral blood stem cell transplantation for acute myelogenous leukemia (it resulted in a solitary pulmonary nodule) and in a patient infected with human immunodeficiency virus (HIV).[60,106] In addition, pneumonic tularemia was noted in a patient with a ventriculoperitoneal shunt.[118] Impairment of normal immunity could prevent adequate protection from *F. tularensis* and could necessitate more prolonged therapy.

DIAGNOSIS

The diagnosis of tularemia is established by a thorough history of possible exposure, clinical manifestations, and serial serologic tests. Obtaining a careful family history often is rewarding because several family members commonly are infected simultaneously. In some instances, however, a positive history never is elicited. Tularemia has no absolute pathognomonic features. In diagnosing tularemia, the physician must account for the endemic rate of the disease in the area, the season of the year, the clinical manifestations of the disease, the precise epidemiologic setting,[135] and the unresponsiveness of the disease to antibiotics that are not effective against tularemia.

The diagnosis is confirmed by the standard agglutination test, which is available commercially and is reliable. Unfortunately, it may not provide an early diagnosis because agglutinating antibodies may not be detectable until the second week of illness. Occasionally, seroconversion is not confirmed until the patient has experienced 4 to 6 weeks of illness. In rare cases, agglutinating antibody may never be detected. A fourfold increase in convalescent titer confirms the diagnosis (with an initial minimum titer of 1:160), but a presumptive diagnosis should be considered in patients with acute titers of 1:160 or greater. This titer may indicate current or past infection, but in a clinically suspicious case, it should be considered an indication for presumptive therapy. Titers of 1:1280 or greater often develop in patients with active disease as the initial manifestation of seroconversion. The agglutination test is specific, but cross reaction with *Brucella* spp., *Legionella* spp. or other gram-negative bacteria can occur. Antibiotic therapy does not prevent the development of agglutinating antibodies. A single titer of 1:128 or greater determined by microagglutination or with a fourfold increase with convalescent testing is also considered positive.

Polymerase chain reaction (PCR)–based assays have been used for early detection of *F. tularensis* infection.[81,95] The PCR test has been shown to be effective in establishing the diagnosis of tularemia even when samples of a tularemic ulcer were obtained 1 to 14 days after infection.[130] When PCR and culture of the wound and blood were compared with agglutination tests, the sensitivity of PCR was 75 percent, and the sensitivity of culture was 62 percent.[79] In addition to increasing the safety for laboratory personnel, the PCR method was more sensitive and could detect infection at earlier stages. In contrast to conventional PCR-based assays, real-time PCR (RT-PCR) has been shown to be more specific and 10 times more sensitive.[150] These assays are not widely commercially available at this time.

In a Norwegian field study, a rapid immunochromatography assay proved inexpensive, time efficient, and portable in contrast to PCR and enzyme-linked immunosorbent assay (ELISA), but this method was less sensitive than PCR.[11] This assay could accelerate identification and treatment decisions in clinical practice.

Gram-stained smears of patient specimens such as exudate and sputum usually do not reveal the organism. However, collecting the specimens poses no danger, and examination of direct smears helps rule out other causative agents. Specimens should not be cultured for *F. tularensis* in the usual hospital or diagnostic laboratory because isolation of these organisms in facilities other than a level P-3 laboratory is hazardous to laboratory personnel. If confirmation by culture is indicated, physicians should notify the laboratory of the potential for the specimen to contain *F. tularensis*, so that appropriate laboratory precautions can be taken.

The differential diagnosis of tularemia depends on the clinical form of the disease. Ulceroglandular and glandular tularemia must be differentiated from disease caused

by ordinary bacterial pathogens such as *Streptococcus* and *Staphylococcus*, from disease caused by *M. tuberculosis* and atypical mycobacteria such as *Mycobacterium marinum*, and from anthrax, HIV infection, and cat-scratch disease. In older patients with inguinal lymphadenopathy, lymphogranuloma venereum, granuloma inguinale, and other sexually transmitted infections should be considered. Occasionally, sporotrichosis and infectious mononucleosis are diagnosed in these patients. Oculoglandular fever is somewhat more distinctive, but the possibility of disease caused by common bacterial pathogens, *L. monocytogenes* infection, herpes zoster, inclusion conjunctivitis, and keratoconjunctivitis must not be ruled out. Oropharyngeal tularemia must be differentiated from streptococcal tonsillopharyngitis and corynebacterial disease. Typhoidal tularemia can be confused with ordinary bacteremia and must be differentiated from the more common bacterial and enteric disease, as well as from malaria, miliary tuberculosis, brucellosis, and typhoid fever. Tularemic pneumonia must be differentiated from other bacterial as well as nonbacterial pneumonia, including tuberculosis, *Mycoplasma* infection, legionnaires' disease, psittacosis, viral pneumonia, Q fever, fungal infection, and chemical pneumonitis.

TREATMENT

Gentamicin is recommended for the treatment of tularemia. The dosage for children is 5 mg/kg daily in two divided doses either intravenously or intramuscularly. The duration of therapy is usually 7 to 10 days, with more severe disease requiring a longer duration of treatment. In mild to moderate cases in which patients become afebrile within 48 hours of starting antimicrobial therapy, a 5- to 7-day course can be used. Defervescence and alleviation of other signs and symptoms occur promptly, usually within several days. Response may be delayed if the lymph nodes have progressed to suppuration requiring drainage

If available, streptomycin given intramuscularly also can be used. The recommended dose of streptomycin is 30 to 40 mg/kg/day administered intramuscularly in two divided doses for 7 days. If a patient has mild symptoms initially or responds dramatically to therapy, an alternative streptomycin regimen of 30 to 40 mg/kg/day for 3 days followed by 15 to 20 mg/kg/day for 4 days may be given intramuscularly. In severe cases or if a child does not become afebrile and asymptomatic within a few days of therapy, extension of treatment beyond 7 days is indicated. Streptomycin-resistant strains of tularemia are reported, but they are rare. Other aminoglycosides (e.g., tobramycin) are ineffective in treating tularemia and should not be used.

Bacteriostatic agents such as tetracycline and chloramphenicol have been used to treat tularemia, with cure rates of 88 percent and 77 percent, respectively. However, these agents are considered suboptimal for the treatment of tularemia because of a high incidence of relapse after therapy is stopped (i.e., 12% for tetracycline and 22% for chloramphenicol).[41]

Although in vitro susceptibility testing indicates that the third-generation cephalosporins may be effective against *F. tularensis*, one report showed treatment failure in 8 children given ceftriaxone.[32] Treatment with other antibiotics has been reported sporadically in the literature.[63,91] Fluoroquinoles have been used with success when treating infections caused by the subspecies *holartica*.[4,104,106,126,139] An efficacy trial in Sweden of ciprofloxacin demonstrated successful outpatient management of *F. tularensis* in 10 of 12 patients 1 to 10 years of age.[80] The dosage used was 15 to 20 mg/kg/day in two divided doses for a 10- to 14-day course of therapy. Defervescence occurred on the fourth day of treatment. The lack of successful treatment data for the subspecies *tularensis* and the issues related to the use of fluoroquinolones in children younger than 18 years of age limit the use of these medications in North American children at this time.

Hearing screening should be considered before initiation of streptomycin or gentamicin therapy. If the child has preexisting hearing loss, the alternative streptomycin regimen or gentamicin therapy can be considered, with close monitoring of serum levels in severe cases. In these cases, audiologic evaluation is indicated after therapy is initiated.

Bed rest and supportive therapy are, of course, indicated. In a severely ill patient who shows signs of endotoxic shock, appropriate monitoring and admission to an intensive care unit are indicated and corticosteroid therapy should be considered. Suppurative lymph nodes may require surgical drainage. Complicated cases (e.g., meningitis) may require treatment with more than one antimicrobial agent.

Before the advent of effective antimicrobial therapy, tularemia often was a protracted illness that lasted weeks or months. Subsequently, a long period of convalescence was necessitated by debility. Antibiotics have interrupted the natural history of the disease. When the disease is diagnosed promptly, the course generally is less than a month. As a result of administering appropriate antibiotic therapy, the mortality rate has declined from 5 to 30 percent to less than 1 percent, except in cases of fulminant pneumonic and typhoidal disease.

PREVENTION

Prevention of human tularemia depends on prevention of exposure to either the vectors or contaminated animal tissue. Children living in areas of tick endemicity should have their skin and hair checked frequently for ticks. Ticks should be removed carefully with tweezers (not with fingernails) by pulling perpendicular to the skin where the ticks have attached.[107] Care should be taken not to squeeze the ticks between the fingers. Persons living in tick-infested areas should wear clothing with tightly fitting cuffs at the wrists and ankles when staying outdoors. Tick repellents should be used with caution on children. Prophylaxis with antimicrobial agents has not proved effective in preventing disease in children with tick bites.

Children should be warned against handling sick or dead rodents or rabbits. Incineration or burial should be

used to dispose of rabbits caught by household pets. Rubber gloves should be worn for preparing game animals, and the meat should be cooked thoroughly before eating. Hunters, especially rabbit hunters, should take precautions against contracting tularemia. A wide range of approaches to vaccine development are being evaluated, but no vaccine against tularemia is currently licensed.[27]

CHAPTER 133

Haemophilus influenzae

Stephen J. Barenkamp

Relatively few species of the genus *Haemophilus* are pathogenic to humans, and nearly all that cause human disease are either encapsulated or unencapsulated strains of *H. influenzae*. These latter bacteria are small, gram-negative pleomorphic coccobacilli that generally are considered to be normal constituents of the microbial flora of the upper respiratory tract of humans.[231,262] Strains without polysaccharide capsules often cause infections of mucosal surfaces, such as otitis media, bronchitis, conjunctivitis, sinusitis, and types of pneumonia.[286,291] Encapsulated strains, especially *H. influenzae* type b (Hib), cause invasive diseases such as septicemia, meningitis, septic arthritis, cellulitis, epiglottitis, pneumonia, and empyema. Before Hib vaccines became widely available, *H. influenzae* was the leading cause of bacterial meningitis in the United States and most other countries and it also was an important cause of other bacteremic illnesses, primarily in young children.[50,252,459]

The organism now known as *H. influenzae* first was described in 1892 by Robert Pfeiffer, who isolated it from the lungs and sputum of patients during the 1889 to 1892 pandemic of influenza. He proposed that the organism

was the cause of influenza, and it initially was known as the Pfeiffer influenza bacillus.[329] The bacteria were difficult to culture on routine media until investigators appreciated that supplementation with X (hemin) and V (nicotinamide adenine dinucleotide [NAD]) factors was required for its growth. By the turn of the century, the organism had been recovered from the blood and cerebrospinal fluid (CSF) of young children with meningitis. Although doubts remained about the etiologic role of the Pfeiffer bacillus as the cause of influenza, not until the influenza pandemic of 1918 was its etiologic role questioned seriously. In 1920, the organism was renamed *Haemophilus influenzae* to acknowledge its inappropriate historic association with influenza and to emphasize its requirement of blood factors for growth (from the Greek *haemophilus*, or "blood loving").[461] In 1933, the viral etiology of influenza was discovered, which refuted any remaining confusion about the erroneous association between *H. influenzae* and influenza virus.

Key concepts relevant to the development of treatment and prevention modalities derive from the pioneering work of Margaret Pittman in the early 1930s.[333,334] Paralleling earlier research on the pneumococcus, she defined two major categories of *H. influenzae*: encapsulated and unencapsulated strains. Among the encapsulated strains, she characterized six distinct serotypes (designated a through f), which now are known to differ biochemically in the composition of their polysaccharide capsules (Table 133-1). She observed that Hib strains were recovered primarily from the blood and CSF of young patients with meningitis and that unencapsulated strains and other *H. influenzae* serotypes were recovered primarily from respiratory tract secretions. Furthermore, she demonstrated that antibody to Hib capsule conferred type-specific protection against lethal infection in rabbits. This observation led to the use of antiserum prepared by immunization with formalin-killed Hib, initially in horses and later in rabbits, as the first treatment of disease. Before this development, Hib meningitis and other forms of invasive Hib disease were almost always fatal.[418] However, not until the late 1930s did treatment of meningitis with both Hib antiserum and sulfonamides substantially reduce the case-fatality rate in children.[7,8]

In 1933, Fothergill and Wright[130] described the age-related risk for acquiring *H. influenzae* meningitis, which affected mostly children younger than 5 years of age. Importantly, they noted the correlation between the age-related risk for disease and the absence of bactericidal antibodies. Later researchers identified antibody to Hib capsule as the major antibody contributing to the protective activity of bactericidal serum.[199,372] These observations suggested that naturally acquired type b anticapsular antibody is protective and that early stimulation of protective immunity with vaccines might be possible. Unfortunately, the advent of effective antimicrobial agents focused attention away from the need for primary prevention. Even with effective antimicrobial therapies and excellent hospital care, significant mortality (approximately 5%) and neurologic morbidity (approximately 20%) remained.[97,98] Ultimately, appreciation that the morbidity and mortality of the disease could never be eliminated completely by treatment gave impetus to the development of vaccines for prevention.

In the early 1970s, investigators purified and characterized the type b capsular polysaccharide (polyribosylribitol phosphate [PRP]) and proposed it as a potential vaccine candidate. Subsequently, the protective efficacy of a PRP vaccine against invasive Hib disease was demonstrated in older children in a 1974 field trial conducted in Finland.[321] This and other studies culminated in the licensure of PRP vaccine in the United States in 1985, thus rendering it the first vaccine available for the prevention of Hib disease.[65] Unfortunately, this vaccine induced equivocal immune responses and incomplete protection in older children and provided no protection for young infants, those at greatest risk for acquiring Hib disease.[447] Improved vaccines used polysaccharide-protein conjugate techniques, and four such vaccines were licensed for use in children. Three of these vaccines were shown to protect young infants against Hib disease[38,362,430]; and with the universal immunization of young infants, invasive Hib disease nearly has been eliminated in many populations.[4,37,322] Unfortunately, Hib disease continues to be a significant cause of morbidity and mortality among children in a number of resource-poor countries around the world where access to Hib vaccines is still limited.[277,435,450]

MICROBIOLOGY

Morphologic and Cultural Characteristics

H. influenzae is a small gram-negative coccobacillus that in clinical specimens can appear filamentous or

pleomorphic, especially when obtained from patients who previously have received antibiotics. The organism is nonmotile, non–spore forming, and facultatively anaerobic and requires two supplemental factors for in vitro growth.[231] The X factor (hemin) is a heat-stable, iron-containing protoporphyrin essential for activity of the electron transport chain, which is important for aerobic growth. The heat-labile V factor (NAD) is a coenzyme. Both factors are present within erythrocytes and are released by appropriate heating or enzyme lysis of the red blood cells, which permits growth on chocolate agar. The requirement for these factors for growth remains the primary basis for the laboratory differentiation of *H. influenzae* from other *Haemophilus* species.[21,231]

The growth of *H. influenzae* is fastidious, and clinical specimens need to be inoculated promptly onto appropriate media, such as chocolate agar.[231] The organism can be grown in most enriched liquid or solid media supplemented with X and V factors. Although not mandatory for growth, 5 to 10 percent carbon dioxide makes some strains grow better. In blood or liquid media, *H. influenzae* may not grow to sufficient quantity to result in visual turbidity; therefore, to detect positive cultures, blood and CSF cultures should be assayed for release of carbon dioxide or routinely subcultured at 24 to 48 hours. After overnight incubation on solid media, colonies appear that are 0.5 to 1.5 mm in diameter and usually rough or granular. Encapsulated strains generally produce slightly larger colonies that are mucoid or glistening. Fermentation reactions and other metabolic activities are variable and, therefore, not particularly useful for identification. However, a biotyping scheme based on the metabolism of indole, urea, and ornithine decarboxylase activity has been used to subtype strains.[231]

Capsular Polysaccharides

Several surface structures of *H. influenzae* contribute to the organism's pathogenicity, but one of the most important is the capsular polysaccharide. Strains can express one of six unique polysaccharide capsules (a, b, c, d, e, or f) (see Table 133-1) or lack capsule expression completely (nontypeable strains). The Hib capsule is of particular clinical, pathogenic, and immunologic importance because Hib accounts for 95 percent of all strains that cause invasive disease in nonimmunized populations.[50,252,259] The Hib polysaccharide consists of a repeating polymer of ribosyl and ribitol phosphate (PRP) that has a 1-1 linkage.[102] The genes involved in production of the Hib capsule have been cloned and consist of two repeating 17-kb DNA fragments separated by a 1-kb bridge region *(bex A)*[188,219]; 98 percent of Hib organisms tested contain this duplication.[219] Encapsulation often is unstable, with loss of capsule production associated with loss of one 17-kb repeat.[218] These strains produce type b capsule, but in barely detectable amounts. Of importance is that the release of Hib capsular antigen in the body fluids of infected individuals can be detected by specific immunologic techniques (i.e., latex agglutination) that are useful for rapid diagnosis.[204,449] The other capsular serotypes are composed of hexose rather than pentose sugars,[102,103,422,423] and these strains also occasionally result in invasive disease.[149,178,227]

Noncapsular Cell Wall Antigens: Proteins

The cell envelope of *H. influenzae* is typical of other gram-negative bacteria, consisting of a cytoplasmic membrane, a peptidoglycan layer, and an outer membrane that represents the outermost layer of the envelope. The outer membrane contains an array of proteins, lipopolysaccharides, and phospholipids, many of which serve important functional roles for the organisms. Over the past 2 decades, significant advances have been made in our understanding of these many outer-membrane components and their contributions to the pathogenesis of disease.[105,286,291]

Early laboratory investigations of *H. influenzae* identified and characterized a number of major and minor outer-membrane proteins of the organism.* However, an understanding of the functional roles of most of these proteins was lacking. Subsequent studies have helped to clarify the roles in disease pathogenesis of an increasing number of these proteins. Several proteins have been shown to be important for attachment of *H. influenzae* to host respiratory mucosal tissues.[55,61,85,175,281] Other surface proteins have been shown to play a central role in bacterial acquisition of iron, a phenotypic trait critical for survival of the organism in the human host.† Other studies have identified bacterial surface proteins important in resistance of *H. influenzae* to components of the host innate immune system, the first line of defense in the nonimmune host.[92,171,172,174,260] The availability for study of the completed genomes of several representative *H. influenzae* strains[182,187,284,383] has also helped to increase the rate of discovery of other proteins important in disease pathogenesis.

Noncapsular Cell Wall Antigens: Lipo-oligosaccharide

Early studies of *H. influenzae* lipo-oligosaccharide demonstrated that although it differed chemically and structurally from the lipopolysaccharide of Enterobacteriaceae, it shared a number of biologic properties with the latter molecule. Lipo-oligosaccharide purified from Hib produced a dermal Schwartzman reaction, was lethal to mice, caused a febrile response in rabbits, evoked polyclonal B-cell activation, and had limulus lysate activity.[128] In addition, human leukocytes incubated with *H. influenzae* lipo-oligosaccharide generated potent procoagulant activity,[275] a property that may be relevant to understanding the mechanisms responsible for intravascular coagulation in severe infection.

Over the past 20 years, knowledge concerning the genetics, structure, biosynthesis, and role in pathogenesis of the *H. influenzae* lipo-oligosaccharide has increased

*References 31, 283, 285, 290, 305, 387.
†References 6, 196, 212, 261, 278, 466.

greatly. *H. influenzae* lipo-oligosaccharide consists of a conserved triheptose inner core linked via a single 2-keto-3-deoxy-octulosonic acid molecule to lipid A from which there are oligosaccharide extensions (outer core), mainly hexose sugars, that vary from one strain to another.[169,256,257,408] *H. influenzae* lipo-oligosaccharide lacks the repetitive side chains typical of gram-negative enteric bacteria but displays great complexity in its outer core sugars and other substituents such as phosphorylcholine[451,452] and sialic acid.[10,47] Several of these sugars and nonsugar substituents are phase variable.[167,168,452] Phase variation is mediated by translational switching of genes that contain tetranucleotide repeats within the 5′ ends of the respective reading frames.[169,192,452] Phase-variable expression of several of these lipopolysaccharide components has been shown to contribute to the pathogenesis of disease (see later).

IgA Proteases

IgA proteases are bacterial enzymes whose only known substrate is human IgA1. These secreted enzymes cleave the IgA heavy chain at specific sites.[215] IgA proteases are regarded as potentially important virulence factors because mucosal defense is in part IgA mediated. *H. influenzae* produces at least two distinct types of IgA protease that cleave different peptide bonds within the IgA1 hinge region.[282,335] *H. influenzae* strains isolated from patients with disease express higher levels of IgA protease than strains isolated from asymptomatic carriers,[434] again suggesting that IgA protease is an important virulence factor for *H. influenzae*. In more recent work, investigators have identified and characterized another IgA protease gene that is present in about a third of *H. influenzae* strains.[120] This latter gene, designated *igaB*, is distinct from the previously characterized IgA protease gene, and its presence appears to be associated with higher levels of IgA protease expression and with a greater likelihood of causing disease,[120] particularly in patients with chronic obstructive pulmonary disease.[292]

Population Structure

A number of powerful typing techniques have been developed for identifying individual *H. influenzae* strains and defining the relationships between strains.[270,300,328] These techniques have provided valuable information for a variety of epidemiologic studies and have served to define the population structure for *H. influenzae* organisms as a whole.[207,374] Encapsulated *H. influenzae* can be grouped into two distinct primary phylogenetic divisions.[300] Furthermore, the population structure of encapsulated *H. influenzae* is clonal. Most of the invasive disease worldwide is caused by serotype b strains from a limited number of clones.[219] Strains producing serotype c, e, and f capsules belong to single divisions and have no close genetic relationships to strains of other serotypes.[300] Serotype a and b strains occur in both primary phylogenetic divisions, probably as a result of transfer and recombination of serotype-specific sequences of the cap region between clonal lineages.[220,300] In contrast to the encapsulated strains, the unencapsulated or nontypeable *H. influenzae* strains demonstrate substantial genetic diversity.[207,299,328,374] Contributing to the genetic diversity of the nontypeable *H. influenzae* are apparently rather high rates of recombination between individual bacterial strains.[82,142,270,409]

Antibiotic Resistance

Another important feature of *H. influenzae* has been the development of antibiotic resistance. Resistance to a wide variety of antibiotics (sulfonamides, trimethoprim-sulfamethoxazole, erythromycin, tetracycline, penicillin) has been described, but these antibiotics are not essential for therapy. Of greater importance is resistance to ampicillin, first noted in the mid 1970s,[259] because it was the primary antibiotic used for the treatment of disease. Since then, ampicillin resistance has become widespread, with between 5 and 40 percent of all isolates in various parts of the world now resistant.[27,87,184,389] The mechanism of resistance usually involves the production of plasmid-mediated β-lactamase enzyme, and resistant strains often are characterized by their plasmid or β-lactamase enzyme content.[202] Recently, non–β-lactamase–mediated ampicillin and ampicillin–clavulanic acid resistance have been reported among an increasing percentage of isolates from around the world, particularly among nontypeable *H. influenzae*.[87,149,389,420] The resistance in these stains appears to be mediated primarily by alterations in specific penicillin-binding proteins.[27,409,420] Resistance to chloramphenicol usually is mediated by the enzyme chloramphenicol acetyltransferase.[352,439] Although chloramphenicol-resistant strains are rare in the United States, they are more prevalent in some areas of the world, and strains resistant to both ampicillin and chloramphenicol have been reported.[64,316,425] Currently, third-generation cephalosporins are the mainstays of therapy for invasive disease; concern about the potential for increasing resistance to these highly effective agents further emphasizes the need for means to prevent disease.[420]

PATHOGENESIS

Acquisition and Carriage of Organisms

Illness caused by *H. influenzae* infection results from a series of pathogenic events beginning with exposure to the organism followed by colonization of respiratory mucosal membranes.[131] Under natural conditions, *H. influenzae* is exclusively a pathogen of humans, and it usually is transmitted asymptomatically from person to person by transfer of respiratory secretions.[184,314,319] The incubation period is unknown because many transmission cycles may occur before a susceptible person becomes ill. Furthermore, in some individuals, the organism can be carried in the upper respiratory tract for many months before it causes disease.[88,342,392]

Both typeable and nontypeable organisms may be present as part of the normal flora of the upper

respiratory tract.[195] Nearly all individuals (as many as 80%) are colonized at some point with nontypeable strains.[184,319,342] In the prevaccine era, Hib carriage rates were lowest in adults and young infants and highest in preschool-aged children.[424] In a prevaccine era study conducted at a daycare center in Dallas where no invasive infections occurred, the average rate of colonization with Hib was 10 percent.[293] During the 18 months of the study, 71 percent of the children 18 to 35 months of age and 48 percent of the children 36 to 71 months of age were colonized at some time. Carriage rates were substantially higher in households or daycare centers in which a case occurred. For example, colonization prevalence rates among children in daycare centers where a case of invasive disease had occurred were as high as 58 to 91 percent.[158,446] Likewise, within families in which a case of invasive disease occurred, rates of colonization of 60 to 70 percent in siblings and 20 percent in parents were observed.[57,446] Whether the high carriage rates in these exposed semi-closed populations were the cause or the result of disease was not clear.[262,273] Close contact among exposed susceptible individuals, as occurs within families and daycare centers, facilitated the risk for transmission and acquisition of disease.

Despite a low point prevalence of Hib pharyngeal carriage (1% to 5%) in the prevaccine era, most young children became colonized with Hib during the first 2 to 5 years of life.[262,424] Consequently, specific Hib immunity developed in these colonized children.[164,372] Hib strains were demonstrated to persist in the nasopharynx for months[273,293] and often were not eliminated by treatment with antimicrobial agents that did not penetrate into respiratory secretions.[381,382] The relationship between carriage of Hib and the subsequent development of disease and immunity is not well understood. Factors that influence the efficiency of transmission and the ability of the organism to establish colonization also are understood poorly. Two factors that probably potentiate the risk for acquiring infection and invasive disease are the size of the bacterial inoculum[403] and the presence of a concomitant viral infection.[217]

Data derived from animal models of infection may be of some benefit in understanding the dynamic nature of the colonization process. Inoculation of Hib organisms into the nose of infant animals results in local infection.[279,355] In this model system, rhinorrhea was not noted but nasopharyngeal washings revealed numerous polymorphonuclear leukocytes and organisms that reached maximal density in approximately 24 hours. Shortly thereafter, bacteremia could be detected in the animals. With colonization of humans, Hib is found on the surface of the respiratory mucosa. Rarely, an organism can be observed by electron microscopy penetrating through a nasal mucosal epithelial cell.[403] An acute inflammatory response to the submucosal bacteria occurs, but it is not marked. The exact mode of entrance of the organisms into the vascular compartment is unknown, but it is assumed that they enter via lymphatics, probably carried by phagocytic cells, which are found in the submucosa. In support of this hypothesis, Rubin and Moxon[355] detected early transient bacteremia in rats after nasal inoculation.

Pathogenesis of Mucosal Infections

Mucosal colonization and mucosal infections occur much more frequently than do invasive bacteremic infections, particularly in those populations where Hib vaccine is in widespread use. Mucosal infections, most of which are caused by nontypeable *H. influenzae*, still cause considerable morbidity and are associated with substantial health care costs.[363,404,412] Mucosal infections generally involve direct movement of organisms through the nasal ostia to the sinuses, up the eustachian tubes, where they cause otitis media, and down the bronchi, where they cause bronchitis and pneumonia. Bacteremia rarely is involved, and such infections generally are not life threatening. These infections appear to be enhanced by antecedent viral infection,[74,318] eustachian tube malfunction,[406] foreign bodies, or mucosal damage from smoking or other irritants.[359]

A considerable amount of recent research has focused on better understanding of the molecular pathogenesis of mucosal surface infections caused by nontypeable *H. influenzae*. The same principles almost certainly apply to the early steps in mucosal colonization by encapsulated *H. influenzae*. The following model has been proposed to explain early events in the process.[181] After transmission from an *H. influenzae* carrier to a new host,[88] bacteria first come in contact with the upper respiratory tract. Here they must overcome the nonspecific mucociliary defenses if colonization is to persist.[377] *H. influenzae* major outer-membrane proteins, P2 and P5, and probably other factors promote bacterial binding to mucus and help establish an early foothold for the bacteria in the upper respiratory tract.[343,403] Local elaboration of lipopolysaccharide and other bacterial products then causes damage to ciliated cells and further impairs mucociliary function.[442] Subsequently, adhesins including HMW1 and HMW2, Hia, Hap, pili, protein E, and others help mediate direct adherence to nonciliated epithelial cells.* Cleavage of IgA1,[120,292,434] invasion into cells and the subepithelial space,[129,403,407] and phase and antigenic variation of surface antigens facilitate evasion of local immune mechanisms.[107,192,452] Binding and uptake of iron and heme allow organisms to persist on the respiratory mucosa despite the relative scarcity of these nutrients.[261,376,457] In the setting of a viral infection, allergic disease, or exposure to cigarette smoke, bacteria spread from the nasopharynx to other sites within the respiratory tract and produce symptomatic disease.[74,318,406]

Pathogenesis of Invasive Disease

Once mucosal colonization with Hib and other potentially invasive strains has been established, dissemination may occur from the upper respiratory tract mucosa to the bloodstream and then elsewhere in the body.[355] The incidence of invasive disease is a small fraction of the carrier rate for Hib.[293] When dissemination does occur, the organism appears to invade the mucosa by separating the

*References 23, 32, 125, 145, 146, 390, 400.

apical tight junctions of the columnar epithelium and moving intercellularly.[403] The resulting bacteremia initially is low in concentration but steadily increases over the course of hours.[315] The dynamics between bacterial proliferation and clearance are influenced by antibody, complement, and phagocytes, all of which have an effect on the magnitude of the bacteremia.[454] The polysaccharide capsule of Hib is antiphagocytic and a major virulence factor. In the absence of anticapsular antibody, bacteremia increases steadily over a period of hours.[166] When the bacterial concentration exceeds 10^4 organisms/mL, metastatic seeding occurs, especially to the meninges via the choroid plexus. Although meningitis is the most frequently recognized manifestation of invasive Hib disease, other potential metastatic sites include the lungs, joint synovium, pleura, peritoneum, and pericardium.[50,418]

The pathogenic events that lead to pneumonia, cellulitis, and epiglottitis are less well understood, even though these invasive infections are associated with bacteremia. Presumably, pneumonia occurs after the aspiration of a critical number of virulent organisms, epiglottitis involves focal infection of the epiglottis, and cellulitis occurs by secondary seeding of deep subcutaneous tissues via the bloodstream.[147] With all forms of invasive Hib disease, invasion of the bloodstream occurs as either a primary or a secondary event.

Viral interactions enhance the pathogenesis of Hib.[303,411] Influenza virus infection has been shown to reduce neutrophil chemotaxis, bacterial killing, systemic macrophage function, the number of circulating T cells, T-cell blastogenesis, and expression of delayed cutaneous hypersensitivity.[1,2,83] Reduced bacterial killing may be due to a defect in phagosome-lysosome fusion that is maximal 5 to 7 days after viral infection and inoculation of Hib.

Bacteremia in Animal Models

During bacteremia, organisms are cleared continually from the vascular compartment by antibody, complement, and the reticuloendothelial system.[280,355] The balance of these processes determines the magnitude and duration of the bacteremia. If bacterial clearance is stopped by reticuloendothelial blockade, bacterial densities increase to a maximum and death quickly ensues, presumably because of the effects of endotoxin.

Initially, bacterial concentrations are very low (approximately 100 organisms/mL). They then steadily increase in density over the course of the next 24 hours and reach a plateau value.[355,356] In young animals, this plateau level is 10^7 organisms/mL and usually is associated with the features of human sepsis. In older animals, the plateau value is lower: approximately 10^4 organisms/mL. These animals have low-grade fever but a relative paucity of symptoms. This primary bacteremia leads to seeding of serous surfaces, such as the peritoneum, diarthrodial joints, pleura, pericardium, and meninges. Early in the infectious process, organisms can be obtained from all these surfaces, but without an observable inflammatory response; later in the process, an inflammatory response ensues. In experimental animals, the first evidence of an immune response is antibody directed against somatic antigens.

Strains of Hib vary in virulence potential. Furthermore, the other five capsular types or nonencapsulated strains result in only transient, low-level, or undetectable bacteremia, even with large inocula (>10^7 colony-forming units).[470] Complement and the spleen are critical factors for host defense in the rat. Rats depleted of C3 and splenectomized (or with iatrogenic splenic congestion caused by hemolytic anemia) have an increased incidence and magnitude of bacteremia.[71,470] These studies suggest the importance of the alternative pathway of complement (opsonic antibody) and reticuloendothelial phagocytes as determinants of intravascular clearance.

Meningitis

Bacteremia precedes the development of meningitis, except for rare situations in which direct extension of infection from adjacent sinuses or an ear infection occurs. Data from experimental studies in infant rats and infant monkeys support this hypothesis.[279] Both the magnitude and duration of bacteremia are probably the primary determinants of invasion of the central nervous system (CNS). After a critical bacterial concentration is exceeded in blood, Hib appears to enter the CNS via the choroid plexus.[395] This theory is supported by the following: (1) the earliest histopathologic lesion seen in the CNS is choroid plexitis, (2) the choroid plexus is one of the foci seeded from the bloodstream, and (3) bacterial density early in infection is greater in the lateral cerebral ventricles than in other CSF compartments.[395] Furthermore, pulse-chase experiments using tracer strains show that organisms enter the CSF through the choroid plexus and that inflammation of the choroid plexus is a uniform feature of meningitis. Subsequently, organisms infect the CSF and the arachnoid villi of the leptomeninges and cause blockage of CSF return, thereby increasing bacterial density and CSF pressure.[395] Generally, the magnitude of CSF bacterial density correlates with the severity of clinical illness.[117,367] Egress of CSF from the subarachnoid space is by flow through the subarachnoid villi, and bacterial density in CSF can be increased or decreased by manipulating CSF egress, which occurs in meningitis via inflammatory responses. The inflammatory response of the choroid plexus is followed by pachymeningitis, which also inhibits CSF reabsorption and increases pressure. Phlebitis of the cerebral blood vessels and thrombosis can occur. All these events contribute to decreased blood flow to the cortex. The resulting increased bacterial density, inflammation, edema, cranial nerve damage, and overall increased CSF pressure are responsible for the morbidity and mortality associated with meningitis.[98,116,395] Parenchymal invasion of the brain rarely occurs.

IMMUNOLOGY

Resistance to *H. influenzae* infection depends on successful integration of a wide variety of host defenses, including (1) mucosal factors that prevent the organism from attaching and penetrating the respiratory epithelium[232,396,401]; (2) activation of the alternative and classical complement pathways, which leads to killing

of the organism and initiation of other inflammatory responses[402,460]; (3) induction of antibody formation[156,160]; (4) phagocytosis and killing by macrophages and polymorphonuclear cells in tissues, the circulation, and the reticuloendothelial system[35,298,462]; and (5) cell-mediated immunity.[100] Assessing the role of each of these immunologic mechanisms independently or determining which mechanisms are most important in host defense is difficult. Although antibodies are not the sole defense against bacteremia, it has been the research emphasis of vaccine development.[156] The goal has been to induce antibodies that are bactericidal, opsonophagocytic, and ultimately protective. Although usually only antibody is measured in these studies, other immune factors are induced and probably play important roles in protection.

Anticapsular Antibody

Initially, antibody activity was assessed by measuring agglutinin and bactericidal titers of serum. In 1933, Fothergill and Wright[130] suggested that bactericidal activity was responsible for immunity to Hib meningitis and that acquisition of this immunity correlated with the age of the individual. Although antibodies to several surface antigens of *H. influenzae* play roles in conferring immunity to Hib[384], antibody to Hib capsular polysaccharide appears to be of primary importance.[351] Newborns and young infants are at low risk for the development of infection, presumably because they have maternally acquired antibody. Young children at highest risk for acquiring disease have low or undetectable levels of antibody, whereas older children at lower risk have higher antibody levels. By 5 years of age, most children have naturally acquired anticapsular antibody that appears to provide protection,[164,372] although natural exposure also induces antibodies to outer-membrane proteins, lipopolysaccharide, and other surface antigens of the bacteria that contribute to natural immunity. The evidence that anticapsular antibodies protect humans from the acquisition of invasive Hib disease is considerable: they activate complement,[402,460] are opsonophagocytic[306] and bactericidal,[130,306] and protect animals from lethal Hib challenge.[405] Moreover, passive prophylaxis with serum preparations containing anticapsular antibody protects agammaglobulinemic patients[351] and high-risk children from the acquisition of invasive Hib disease.[361] Furthermore, in the preantibiotic era, immune serum was an effective therapy for Hib disease.[7,333] However, the most compelling evidence for the protective efficacy of PRP antibody is the clinical protection achieved in older children vaccinated with purified PRP vaccine[321] and younger infants immunized with Hib conjugate vaccines.[252,322] Induction of antibody to Hib polysaccharide is the immunologic basis of all Hib vaccines.

A precise minimal level of anti-PRP antibody that is protective has not been established.[156] Data from passive protection of agammaglobulinemic children, challenge experiments in infant rats, and studies of naturally acquired antibody levels in healthy individuals of various ages suggest that the minimal serum concentration of anti-PRP antibody that provides protection ranges from 0.05 μg/mL in animals[373] to 0.15 to 1.00 μg/mL in humans.[210,321] Such estimates are crude and do not take into account the different functional properties of different immunoglobulins[160,247] or the contribution of antibodies to other Hib antigens. In addition, antibody levels decline over time and a given peak level may not reflect levels at the time of exposure, which would predict long-term protection better.[16,321] In a Finnish PRP vaccine trial, an antibody level greater than 1.0 μg/mL 1 month after immunization correlated with clinical protection for a minimum of 1 year.[321] However, this antibody level might not be extrapolated readily to the immunogenicity data evaluated in different studies or with different Hib conjugate vaccines.

Class and Subclass-Specific Antibody

Several studies have shown variable immunoglobulin class, isotype, idiotype, and IgG subclass responses to PRP polysaccharide after natural Hib exposure, disease, and immunization.[211,373] Most individuals respond with IgG antibodies after receiving PRP immunization, although some children have predominantly IgA or IgM responses.[211] Schreiber and associates[373] showed that IgG antibody is bactericidal, opsonic for polymorphonuclear leukocytes in the presence of complement, and protective for animals. IgM antibody is equally protective and more bactericidal than IgG in the presence of complement, but it opsonizes poorly. IgA antibody is not bactericidal, opsonic, or protective for animals. Some researchers have hypothesized that IgA-specific antibody blocks the activity of other more functional antibodies and thereby may depress immunity.[297]

Data from experiments in mice and humans suggest that polysaccharide antigens induce restricted IgG subclass responses.[349] The findings of increased susceptibility to Hib disease in IgG subclass–deficient patients (predominantly IgG2 and IgG4 deficiencies)[317,375] and the low levels of IgG2 in children younger than 2 years of age[380] suggest that differences exist in the role of subclass-specific anticapsular antibodies. In adults, natural exposure or immunization with PRP vaccine results in a predominantly IgG2 subclass response.[340] In children, IgG1 and IgG2 antibodies develop after PRP immunization, but IgG1 antibodies predominate after immunization with Hib conjugate vaccines.[12,189,208] Human anti-PRP antibodies express predominantly kappa light chains[414] and may be grouped into a few restricted clonotypes. These clonotypes and antibody specificities have been characterized by idiotype analysis[245,248,388] and amino acid sequencing of the immunoglobulin light chain.[414] Individuals of different ages produce different proportions or repertoires of antibody.[246] Some differences in binding specificity and affinity have been described with the different anti-PRP antibodies,[247,248,369] but whether the antibodies have different degrees of protective potency or are substantially different in proportion in individuals given different vaccines is not clear.

The role of mucosal immunity in killing Hib or inhibiting adherence or penetration of the mucosa is understood poorly, although studies of secretory IgA antibody to the Hib capsule have been conducted.[331,332] Moreover, Hib strains produce IgA proteases that can inactivate

mucosal antibody.[120,282] The observation of reduced carriage of Hib in children given Hib conjugate vaccines[121,195,295,311,410] suggests that mucosal immunity may be important in reducing transmission of the disease.

Cellular Immune Responses

Most of our understanding of the interactions of B cells, T cells, and antigen-presenting cells (macrophages) is derived from extensive research in mice.[91] Based on T-cell involvement in antibody synthesis, antigens can be classified as T-dependent (thymus-dependent) or T-independent immunogens. Most protein antigens induce helper T-cell regulation of antibody synthesis and, therefore, are considered T dependent. These antigens first are recognized and processed by macrophages and then presented to both T and B cells. The activated T cells induce proliferation and differentiation of specific antigen-reactive B-cell subpopulations. They also retain the memory necessary for subsequent booster responses.[33] Through the release of cytokines, helper T cells appear to regulate (1) the magnitude of the immune response, especially in young infants; (2) the switch in immunoglobulin classes (IgM to IgG); (3) the functional activity of antibody; and (4) the capacity to elicit immunologic memory.

Polysaccharides consist of repeating oligosaccharide units and elicit weak immune responses involving minimal T-cell influences.[33] These T-independent antigens elicit antibody responses primarily by direct stimulation of B cells. In general, polysaccharide vaccines have the following T-independent immunologic characteristics: (1) delayed ontogeny of immune responsiveness in the young, (2) limited and variable quantitative immune responses, (3) restricted isotype (predominantly IgM) and IgG subclass responses, and (4) lack of a booster or anamnestic response with secondary antigenic challenge. The quest for a Hib vaccine that is immunogenic and protective in young infants has involved attempts to convert the PRP antigen from a T-independent to a T-dependent antigen by using the carrier-hapten principles first defined by Landsteiner in the first half of the 20th century.[228] PRP can be considered a hapten that is linked covalently to a T-dependent immunogen, a carrier, to form a conjugate vaccine. The Hib conjugate vaccines, which demonstrate markedly enhanced immunogenicity, are described in a subsequent section.

Genetic Factors

When compared with protein vaccines, the immune responses to most polysaccharide antigens are variable and may be influenced by genetic factors. Several studies have shown associations between the immune responses to PRP vaccine and genetically determined factors such as red cell antigens, human leukocyte antigen, or immunoglobulin allotypes.[11,162,379,456] However, because many factors influence immunogenicity, whether these associations have relevance is not known, and establishing controls for them is difficult. In addition, whether the antibody differences are important clinically also is not known. No single genetic relationship regulating susceptibility or the immune responses to polysaccharide antigens has been demonstrated convincingly.

Complement

The importance of complement components in host defense against Hib is substantiated by elimination of the bactericidal activity of serum via heat, by the susceptibility of complement-depleted animals to Hib disease, and by the increased susceptibility of patients with specific congenital complement deficiencies.[86,402,460] Hib is capable of activating both the classical and the alternative complement pathways,[86,402] thereby initiating opsonophagocytosis and cell killing and eliciting other inflammatory responses. Whereas the alternative pathway probably is most important early in the course of infection in a nonimmune host, the antibody-dependent classical complement pathway is more likely to predominate as a defense mechanism at a later stage of infection.[460] Both encapsulated and unencapsulated organisms activate complement, thus underscoring the importance of noncapsular antigens in host defense.[296,298] Although the Hib capsule is a poor activator of the alternative complement pathway, antibody to the capsule activates both the classical and the alternative pathways.[402] Other cell wall antigens activate the alternative pathway, and antibody to these antigens activates the classical pathway.[86,402,460] Thus, antibodies to both capsular and noncapsular antigens activate the complement system, primarily via the classical pathway. Activation of the terminal complement components mediates the bactericidal activity of serum.

Later studies explored the contribution of lipopolysaccharide structure to the susceptibility of *H. influenzae* to complement-dependent serum bactericidal activity.[122,169,250,451] Phase-variable structural modifications to the core lipopolysaccharide structure including additions of phosphorylcholine,[77,452] sialic acid,[378] and other carbohydrate moieties[106,467] all have been shown to influence the susceptibility of these organisms to complement-mediated killing. Related studies in animal models of infection have also demonstrated the importance of these phase-variable lipopolysaccharide modifications to disease pathogenesis in vivo.*

More recent work has focused on the ability of *H. influenzae*, particularly nontypeable strains, to modulate activation of the complement cascade by interacting with human complement regulatory proteins.[174] In the presence of human serum, nontypeable *H. influenzae* strains are able to bind the C4B binding protein,[172] the human complement inhibitor factor H,[177] and vitronectin.[176,391] The presence of these proteins on the bacterial surface protects the organisms against complement-mediated attack and contributes to the survival of *H. influenzae* in the presence of human serum and serum components.[173]

Phagocytosis

Opsonization leading to phagocytosis and killing of *H. influenzae* also is an important determinant of host

*References 47, 122, 197, 229, 419, 451.

defense.[296,298,405,462,464] Impairment of phagocytic function or a reduction in the number of phagocytes results in increased susceptibility to disease, as does loss of the spleen or impairment of its function (e.g., hemoglobinopathies).[72,337] The opsonic activity of serum is influenced greatly by the roles of complement and antibody. Opsonization and phagocytosis of Hib appear to be dependent on (1) IgG binding, (2) antibody activation of the classical complement pathway with deposition of C3b on the bacterial surface, and (3) direct bacterial activation of the alternative complement pathway.[308] Relatively little is known about direct cell-mediated killing of *H. influenzae*.[100]

EPIDEMIOLOGY

Haemophilus influenzae type b

Humans are the only natural host for *H. influenzae*, and asymptomatic nasopharyngeal carriage, usually by unencapsulated strains, is a common finding.[113,262] In the era before widespread use of Hib conjugate vaccines, nasopharyngeal acquisition of Hib strains was also quite common and was shown to increase after infancy and to persist for weeks to months. Most children were colonized at some time during the first 5 years of life.[262] Colonization rates greater than 70 percent occurred after recent exposure in closed populations, such as among family members or daycare center contacts of a patient with disease.[293] Person-to-person transmission occurred via respiratory droplets, and fomites were also thought to play a role. As Hib conjugate vaccine administration has become part of the routine infant immunization schedule in many countries, there has been an associated and pronounced drop in the rate of nasopharyngeal carriage of Hib strains.[195,244,294,311,410]

Before the development of immunization, invasive Hib disease was a leading infectious disease problem worldwide that affected primarily young children (Table 133-2).[440,455,459] Hib strains are responsible for more than 95 percent of invasive infections in children. According to population-based studies, an 20,000 to 25,000 persons acquired invasive Hib disease annually in the United States, 85 percent of which occurred in children younger than 5 years of age.[50] The incidence of Hib meningitis and all invasive Hib disease was 40 to 69 and 67 to 130 cases per 100,000 children younger than 5 years, respectively. Invasive Hib disease developed in an estimated 1 in every 200 children in the United States during the first 5 years of life.[80] Hib pneumonia was estimated to cause as many as 15 percent of cases of ambulatory pneumonia in children younger than 6 years old, but the true incidence was unknown because microbiologic diagnosis is difficult. Overall, the incidence of Hib disease in the prevaccine era was similar to that of paralytic poliomyelitis during its peak epidemic years before immunization. A bimodal seasonal pattern had been observed in several studies, with one peak occurring between September and December and a second peak between March and May.[344,455] The attack rate of Hib was slightly higher in boys.[254]

TABLE 133-2 **Worldwide Incidence of Invasive *Haemophilus influenzae* Type b Disease Before the Use of Hib Vaccines in Children Younger Than Age 5 Years**

Region	Years	Hib Meningitis*	All Hib Disease*

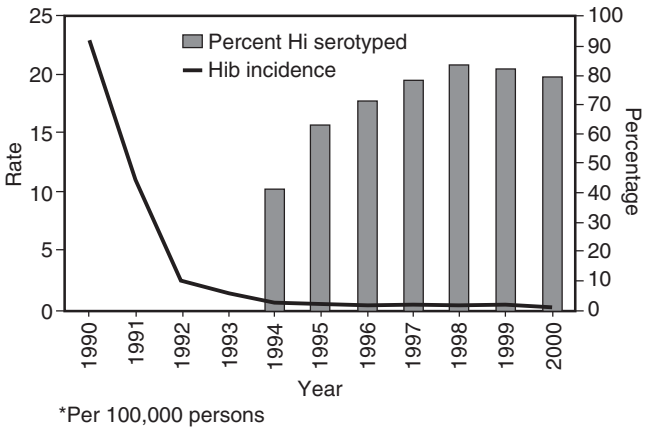

FIGURE 133-1 ■ Incidence rate of *Haemophilus influenzae* type b (Hib) invasive disease per 100,000 persons and the percentage of *H. influenzae* (Hi) isolates serotyped in children younger than 5 years—United States, 1990-2000. (From Centers for Disease Control and Prevention. Progress towards elimination of *Haemophilus influenzae* type b invasive disease among infants and children—United States, 1998-2000. *MMWR Morb Mortal Wkly Rep* 2002;**51**:234–37.)

The widespread use of Hib conjugate vaccines altered the epidemiology of invasive Hib disease dramatically (Fig. 133-1).[252] The first Hib conjugate vaccine was licensed in the United States in 1987 for use in children 18 months or older.[66] Subsequently, decreases in the incidence of Hib disease were seen in older children and, unexpectedly, in unimmunized infants and children as well. This finding was attributed to a direct effect of vaccination on nasopharyngeal carriage, thus decreasing the

environmental burden of Hib infection and, ultimately, the transmission of disease. In late 1990, Hib conjugate vaccines were approved for use in infants beginning at 2 months of age, which heralded a dramatic decline in the incidence of invasive Hib disease in all children.[67] In populations in which immunization rates are high, the development of invasive Hib disease has been eliminated almost completely.[224,252]

Some population-based studies of the incidence of *H. influenzae* disease have been conducted outside the United States, primarily in Western Europe, and they showed an incidence approximately one third to two thirds that in the United States.[323,360,398] The incidence of Hib disease is especially high in certain ethnic groups, including Aboriginal children in central Australia[180,195]; Navajo Indians; Alaskan natives; and Apache, Yakima, Athabascan, and Canadian Indians.[243,252,274,448,469] *H. influenzae* appears to rank as a leading cause of bacterial meningitis in some developing countries as well.[9,56,397,443,468] As seen in the United States, a substantial reduction in Hib disease has occurred with the implementation of widespread vaccination programs.

Children between the ages of 6 and 18 months are at highest risk for acquiring invasive Hib disease[254]; however, the age distribution of specific clinical syndromes of the disease varies. The peak incidence of Hib meningitis occurs in children 6 to 9 months of age and declines markedly after 2 years of age.[134,413] Hib cellulitis tended to occur during the first year of life, whereas epiglottitis generally occurs in unimmunized children older than 2 years of age. Invasive *H. influenzae* disease was seen much less frequently in adults because of the development of protective antibodies over time, but it occurred more frequently in immunocompromised patients. Nonetheless, Hib caused pneumonia and meningitis in adults[114,326] and disease caused by other serotypes and nontypeable strains, especially pneumonia, otitis media, bronchitis, and sinusitis, are common findings in all age groups.[203,224,252,265] Most adults in whom invasive *H. influenzae* disease develops were not immunized as children and have an underlying condition such as chronic obstructive pulmonary disease, human immunodeficiency virus (HIV) infection, alcoholism, pregnancy, or malignancy.[51,114,326]

The development of invasive Hib disease in a given individual is the consequence of a complex interaction of a variety of factors, including the risk for exposure, the characteristics of the organism, and the host.[132] In populations that experienced a high incidence of disease, such as American Indians, the age-specific incidence peaked in a younger age group (<6 months), presumably because of early or intense exposure to Hib at home or in the community.[249] Several factors that may reflect environmental exposure to the organism, such as household size,[157] crowding,[427] attendance at daycare centers,[81,193] low family income,[26,133,134] and low parental education level,[133,134] have been shown to be risk factors for the acquisition of disease, whereas breast-feeding appears to be protective.[327] Several underlying medical conditions are associated with an increased risk for the acquisition of Hib disease, including HIV infection,[62,368] sickle-cell anemia,[337] asplenia or splenectomy,[72] antibody[115] and complement deficiency syndromes,[123] and malignancy.[453]

Although the direct contagiousness of invasive Hib disease is limited, small outbreaks and direct secondary transmission of disease can occur.[57,445,446] Numerous studies have estimated the risk for developing secondary disease in household contacts in the 30 days after the onset of disease in an index case. Overall, the attack rate for contacts of all ages in the prevaccine era was 0.3 percent, which represents a risk approximately 600-fold higher than the age-adjusted risk in the general population.[57,445] However, attack rates varied inversely with age, with children younger than 4 years being at greatest risk. Among household contacts, nearly two thirds of secondary cases occurred within the first week after the onset of disease in the index patient.[413] Controversy exists about the degree of risk for the development of secondary Hib disease in daycare center contacts exposed to a child with invasive Hib disease. Such risk in unimmunized children younger than 2 years of age ranged up to 3.2 percent,[26,314] whereas for those older than 2 years it was less than 1 percent.

A trend causing concern several years ago was the reappearance or persistence of Hib disease in highly immunized populations.[22,195,226,252,393] The factors contributing to these problems are still the subject of debate, but with the reemergence of Hib disease in the United Kingdom in the late 1990s, attention focused on the lack of a booster dosing of infants as part of the regular immunization series and the decreased immunogenicity of combination vaccines in which the Hib conjugate vaccine was combined with acellular pertussis vaccine components.[226,268] The Alaskan experience raised different concerns.[393] However, in this latter population unique characteristics of Hib nasopharyngeal carriage in the rural population and variability in the antibody response of young infants to different Hib vaccines appeared to be the factors most critical to explaining persistent Hib disease in Alaskan natives.[252,392,393]

Non–type b Encapsulated *Haemophilus influenzae*

H. influenzae organisms expressing one of the five non–type b capsular types are also carried in the nasopharynx of a small percentage of the population.[88,262] With the success of the Hib conjugate vaccine in preventing invasive disease caused by type b organisms, there was concern that disease caused by other encapsulated strains might become more prevalent.[67] There were several reported clusters of invasive disease caused by *H. influenzae* type a over the past decade,[5,53,205,326,347] as well as occasional cases of disease caused by other serotypes.[203,224,313,426] However, surveillance studies for the most part have failed to document a sustained increase in the incidence of disease caused by non–type b serotypes after introduction of the Hib conjugate vaccines.[203,224,252,265] These data suggest that the concern about serotype replacement may be more theoretical than real.

Nontypeable *Haemophilus influenzae*

Asymptomatic colonization of the mucous membranes of the upper respiratory tract by nontypeable *H. influenzae*

strains is very common, occurring in 60 to 90 percent of young children.[221] Infants often become colonized with nontypeable *H. influenzae* early during the first year of life.[111] Nasopharyngeal colonization is a dynamic process characterized by relatively rapid turnover of individual strains and, not infrequently, simultaneous carriage of several distinct clones.[28,88,113,223,374] With increasing age, nasopharyngeal carriage of nontypeable *H. influenzae* becomes less frequent, but it is still present in a significant percentage of the population.[221,374] Nontypeable *H. influenzae* organisms are only rarely associated with invasive disease[28,108,309,385,433] but are a common cause of mucosal surface infections such as otitis media, sinusitis, bronchitis, and occasionally pneumonia.[234,286,291,330]

CLINICAL MANIFESTATIONS

Bacteremia

Occult bacteremia (i.e., not associated with a primary focus of infection) is not a common occurrence with Hib, but bacteremia does precede essentially all invasive Hib infections. In the prevaccine era, Hib was the second leading cause, after *Streptococcus pneumoniae*, of occult bacteremia primarily affecting children 6 to 36 months of age.[15] Most children initially have fever and peripheral leukocytosis. Unlike *S. pneumoniae* bacteremia, the condition is not benign. In 30 to 50 percent of children with occult Hib bacteremia, a focal infection such as meningitis, pneumonia, or cellulitis develops.[84,216]

Meningitis

Meningitis is the most serious manifestation of invasive Hib disease; however, no clinical feature differentiates Hib meningitis from other causes of bacterial meningitis in children.[116] The onset of disease can be fulminant,[194] but more commonly the signs and symptoms are nonspecific (particularly in young infants) and may include irritability, fever, lethargy, poor feeding, or vomiting. Children younger than 18 months often do not have nuchal rigidity. Older children are more likely to have findings of headache, photophobia, and meningismus. With fulminant Hib meningitis, very rapid neurologic deterioration may occur with increased intracranial pressure, seizures, coma, and respiratory arrest.[116] Ten to 20 percent of children with meningitis will have other foci of infection, such as cellulitis, arthritis, or pneumonia,[25,124] and essentially all have concomitant bacteremia.

CSF examination typically reveals a pleocytosis (mean of 4000 to 5000 white blood cells/mm^3) with a predominance of polymorphonuclear leukocytes.[98] Approximately 75 percent of patients have hypoglycorrhachia, and around 90 percent have an elevated CSF protein concentration. Eighty percent of meningitis cases caused by Hib will have a positive CSF Gram stain. As with other types of bacterial meningitis, however, previous antimicrobial therapy significantly decreases the concentration of Hib organisms in the CSF and diminishes the sensitivity of Gram staining.[39] Previous treatment does not affect the total blood cell count and differential count, glucose value, or protein level substantially, thus permitting a diagnosis of meningitis. In more than 90 percent of cases, capsular antigen can be detected in CSF or serum.[449] Anemia, leukocytosis, thrombocytosis, and thrombocytopenia also are observed frequently.[116]

Complications of Hib meningitis include seizures, cerebral edema, subdural effusions or empyema, inappropriate secretion of antidiuretic hormone, cortical infarction (often manifested by focal neurologic abnormalities), cerebritis, intracerebral abscess, hydrocephalus, and, rarely, cerebral herniation.[44,98,116,336] Computed tomography and magnetic resonance imaging of the head should not be performed routinely for Hib meningitis, but these studies may be helpful if focal neurologic findings are present or if the clinical course becomes complicated. Small subdural effusions are common findings but are not usually of clinical significance.[116]

Even with prompt intensive care, the mortality from Hib meningitis is approximately 5 percent, and significant long-term morbidity, including sensorineural hearing loss, delay in language acquisition, developmental delay, gross motor abnormalities, vision impairment, and behavior abnormalities, may occur in 15 to 30 percent of survivors.[97,98,116,336,415] A substantial proportion of such abnormalities may resolve over time, thus emphasizing the need for long-term monitoring of these patients.[116]

Pneumonia

Hib pneumonia is clinically indistinguishable from other bacterial pneumonias.[148,438] Most patients have a preceding upper respiratory tract infection, fever, and cough accompanied by peripheral leukocytosis with a predominance of polymorphonuclear leukocytes. Radiologically, Hib pneumonia may be segmental, lobar, interstitial, or diffuse, and many cases have evidence of pleural or pericardial involvement on radiographic examination. Cavitation and pneumatoceles are rare occurrences but have been reported.[14,73] Computed tomography or magnetic resonance imaging can be useful adjuncts to the evaluation of complicated disease caused by Hib.[79] Blood, pleural fluid, tracheal aspirate, and lung aspirate cultures are positive in 75 to 90 percent of cases. Detection of capsular polysaccharide in pleural fluid, serum, or urine can establish the diagnosis, particularly if antimicrobial therapy had been instituted previously. Although fever may persist for several days while the patient is receiving adequate therapy, uncomplicated Hib pneumonia rarely is associated with long-term pulmonary dysfunction. In the developing world, in addition to disease caused by Hib, pneumonia caused by nontypeable *H. influenzae* is a continuing problem[140,233] that is also associated with significant morbidity and mortality.

Epiglottitis

Acute upper airway obstruction caused by Hib infection of the epiglottis and supraglottic tissues occurred in the prevaccine era primarily in children 2 to 7 years of age.[34,269] Its onset usually is abrupt, with high fever, sore throat, dysphagia, and sepsis. Antecedent upper respiratory tract infection with cough occurs in approximately

50 percent of patients.[49,242] The child may drool because of an inability to swallow oropharyngeal secretions, and progressive respiratory distress with tachypnea, stridor, cyanosis, and retractions may develop over a period of hours. The child usually is agitated and may sit forward with the chin extended to maintain an open airway. In children younger than 2 years of age, Hib epiglottitis may be manifested in an atypical fashion, with low-grade fever and a cough suggestive of croup.[242]

The most important aspect of the management of a child with epiglottitis is maintenance of a patent airway. Nasotracheal intubation is preferable to tracheostomy because it is equally effective, is not permanent or disfiguring, and has fewer inherent risks.[34] Seventy to 90 percent of patients with epiglottitis will have positive blood cultures; tissue for culture of the inflamed epiglottis should be obtained only after the airway has been secured. A lateral neck radiograph revealing dilatation of the hypopharynx and the "thumbprint" sign (swollen epiglottis)[46] can be helpful if the clinical findings are subtle, but in most cases diagnostic studies should not delay intubation and direct inspection of the epiglottis in controlled surroundings. The mortality rate is 5 to 10 percent, and death is almost always caused by abrupt airway obstruction.

Joint Infection

Before the routine use of Hib conjugate vaccines, Hib was the leading cause of septic arthritis in children younger than 2 years of age.[124] It affects a single large joint at the knee, ankle, elbow, or hip in more than 90 percent of cases. Contiguous osteomyelitis occurs in 10 to 20 percent.[124,230] No feature clearly distinguishes septic arthritis caused by Hib from that of other bacterial causes. Patients initially are febrile, and more than two thirds have decreased range of motion, local warmth, and swelling.[89,124,230] Usually, pain, swelling, and erythema of the involved joint are preceded by a nonspecific upper respiratory tract illness. The clinical features may be subtle, with only decreased range of motion of the joint or abnormal gait as the initial finding. Hib capsular antigen concentrations are very high in the infected joint fluid of children with septic arthritis, and rapid detection of antigen is useful diagnostically. Septic arthritis of the hip requires surgical drainage, and resolution generally is rapid, but long-term cartilage damage may result from Hib arthritis despite adequate therapy.[415]

Cellulitis

Cellulitis is a relatively uncommon form of Hib disease and was seen in the prevaccine era almost exclusively in children younger than 2 years of age. Most cellulitis (74%) is located in the cheek (buccal cellulitis), the periorbital region, and the neck[89] and rarely on the extremities. Facial cellulitis occurs most commonly in infants and is manifested as acute fever and a unilateral, raised, warm, tender, and indurated area that may progress to a violaceous hue, although this finding is not unique to Hib disease.[417] Aspirate cultures of the point of maximal swelling usually yield the organism, and bacteremia is a typical finding.[126,191] A secondary focus (including meningitis) may be present in 10 to 15 percent of patients.[25] Orbital cellulitis generally is a complication of ethmoidal sinusitis and, consequently, can be caused by non-Hib strains. An etiologic diagnosis can be established by blood culture or aspiration of subcutaneous tissues. Antibiotics always are indicated, but the need for surgical drainage depends on the degree of involvement of the tissues within the orbit.

Pericarditis

Hib pericarditis usually is a complication of adjacent pneumonia and is characterized by fever, an ill appearance, respiratory distress, and tachycardia.[70,101,348] The radiographic or clinical diagnosis can be confirmed by two-dimensional echocardiography[465] and may be suggested by finding capsular polysaccharide in serum or pericardial fluid or in Gram-stained pericardial fluid. Cultures of pericardial fluid are positive in more than 70 percent of cases.[89] Early drainage is an important part of the management of this illness, and early pericardiectomy or pericardiostomy is preferred over repeated pericardiocentesis.[276,348]

Neonatal Disease

H. influenzae causes 2 to 8 percent of neonatal early-onset sepsis.[58,186,441] Most of these cases are caused by nontypeable strains, most of which are concordant with those isolated from the maternal genital tract.[441] The precise pathogenesis is unknown, but neonatal disease often is associated with prematurity, low birth weight, premature rupture of membranes, and maternal chorioamnionitis; several cases have occurred after cesarean delivery, thus suggesting in utero transmission.[357] Clinical manifestations include pneumonia, bacteremia, and conjunctivitis. More than two thirds of neonatal *H. influenzae* disease occurs on the first day of life, with an overall mortality rate of 55 percent.[137]

Other Invasive Infections

Other invasive Hib infections include endophthalmitis,[416] CSF shunt infections,[236,345] necrotizing fasciitis, pyomyositis,[302] peritonitis,[76,136] scrotal abscess,[241] brain abscess,[119] polyserositis,[271] tenosynovitis,[301] epididymitis,[165] lung abscess,[240] periappendiceal abscess,[264] and bacterial tracheitis.[59] Invasive disease also may be characterized by fever alone, fever with petechiae, or fever of unknown origin.[52,432]

Diseases Caused by Non–type b *H. influenzae*

Respiratory tract infections associated with nontypeable *H. influenzae* are a major cause of morbidity and mortality today in both developed and nonindustrialized nations.[233,440] Previously, invasive disease caused by nontypeable *H. influenzae* was rare and generally associated

with underlying medical conditions such as prematurity, malignancy, cystic fibrosis, asthma, leakage of CSF, CNS shunts, congenital heart disease, lymphoproliferative disorders, and immunoglobulin deficiency.[112,143,307] More recently, with a decline in the rate of infections caused by Hib, other *H. influenzae* serotypes such as types a, e, and f, and nontypeable strains have become relatively more common causes of both mucosal surface infection and invasive disease,[203,205,224,265,421] although it is unclear that the absolute incidence of disease has increased.[252] There have been several reports of invasive disease clusters caused by *H. influenzae* type a.* One such report suggested that a IS1016-bexA deletion present in the chromosome of the recovered type a strains, a deletion similar to that present in many Hib strains,[219] might be a marker for more virulent type a clones.[5] Other serotypes have also been reported as causing cases of non–type b invasive disease.[203,224,252,313] Urwin and associates[426] identified 91 cases of invasive *H. influenzae* type f disease in a multistate area over the course of a 6-year period. The incidence of invasive type f disease was 0.5 cases per 1 million population in 1989 and 1.9 cases per 1 million population in 1994. In children, pneumonia and meningitis each accounted for 40 percent of the total cases. Overall, mortality from type f *H. influenzae* disease was 21 percent in children. Serotype f also has been reported as a cause of endocarditis[135] and septic arthritis[150] in healthy, normal children.

Invasive disease in children caused by nontypeable *H. influenzae* has also been reported.[60,108,307,433] Heath and associates[185] conducted an active prospective surveillance study of *H. influenzae* infections in the United Kingdom and Republic of Ireland. During the study period (October 1992 to December 1998), 102 cases of invasive disease caused by nontypeable *H. influenzae* were reported. Children with nontypeable *H. influenzae* infection were compared with those who had Hib disease. The former were more likely to be younger (16 vs. 22 months) and more likely to have pneumonia and bacteremia (p <.001) than were those with Hib disease. In 1998, the incidence of non–type b *H. influenzae* disease in all children younger than 5 years of age in the United Kingdom was 1.3 per 100,000 versus 0.6 per 100,000 population for Hib disease. Most non–type b strains isolated were nontypeable.

Mucosal Infections

Unencapsulated or non-Hib strains cause a variety of mucosal infections, including otitis media, sinusitis, conjunctivitis, and bronchitis.[214,234,291] Nontypeable *H. influenzae* otitis media has clinical features similar to otitis media caused by other common middle ear pathogens including fever, symptoms referable to the upper respiratory tract, and nonspecific symptoms such as irritability, vomiting, and diarrhea.[235] Recent data suggest that nontypeable *H. influenzae* is the most common cause of acute otitis media and persistent or recurrent otitis media in children who have received the pneumococcal conjugate vaccine.* Sinusitis caused by nontypeable *H. influenzae* may be manifested as common cold symptoms that are persistent or more severe than usual.[436,437] Older children and adults are more likely to complain of headache and paranasal, dental, or facial pain. Other common symptoms are a daytime cough that may worsen at night or reactive airway disease unresponsive to therapy. Rarely, chronic otitis or sinusitis may result in the development of mastoiditis or a parameningeal abscess.[206] Conjunctivitis usually is bilateral and purulent and may occur in outbreaks.[41-43] Although common, these infections rarely are life threatening and are not associated with bacteremia.

DIAGNOSIS

A high index of suspicion for the possibility of Hib disease must be maintained when evaluating children with appropriate clinical manifestations and findings. The primary criterion for the diagnosis of *H. influenzae* infection is Gram stain or isolation of the organism from an infected focus (e.g., CSF, pleural fluid, sputum, or blood). Because most invasive Hib disease is associated with bacteremia, blood cultures should be performed for any febrile child with potential Hib disease.[216] The specimens need to be processed immediately because the organism is fastidious. Although most commercial blood culture media support the growth of *H. influenzae*, the inoculum should be applied, when possible, directly to chocolate agar or a semisynthetic medium containing hemin and NAD.[21,139,231,325] In liquid medium, growth may not be sufficient to result in turbidity; therefore, for blood cultures, advanced detection systems or subcultures should be performed.[231] In addition, selective media that suppress the growth of gram-positive organisms may increase the recovery of *H. influenzae* from upper respiratory tract specimens.[69] Identification of an isolate as *H. influenzae* relies on its dependence on heme and NAD.[231] Determination of the capsular type expressed by *H. influenzae* is important both for clinical and epidemiologic purposes. Traditionally, this has been performed by slide agglutination with capsular type-specific antisera and suspensions of bacterial organisms.[231] Recently, polymerase chain reaction–based techniques that target the capsular gene locus have been developed that accurately identify strains expressing the six recognized capsular types.[251,304]

Other techniques that may assist in microbiologic diagnosis include rapid antigen detection, staining techniques, and immunofluorescence.[204,258,449] Such techniques are useful in the context of a patient whose cultures are sterile because of previous antibiotic therapy, or they can confirm the clinical diagnosis before bacterial growth occurs. The three techniques most commonly used in the past for antigen detection were latex particle agglutination (LPA), countercurrent immunoelectrophoresis, and coagglutination. False-positive results on CSF were rare for all three tests but did occur when testing serum and

*References 5, 53, 178, 179, 205, 313.

*References 40, 63, 200, 324, 330, 458.

urine. LPA appeared to be the most sensitive of the three tests and is the only one that remains in common use today. False-positive results can occur in the urine of children with nasopharyngeal carriage of the organism or, more commonly, for several days after immunization with Hib conjugate vaccine.[399] Acridine orange is a fluorescent stain that binds to cellular nucleic acids and may be useful in situations in which smaller bacterial concentrations are present.[213] Immunofluorescent staining of purulent specimens from patients with partially treated disease also has been useful.[78]

TREATMENT

Invasive Disease

Bacteremia plays a central role in the pathogenesis of invasive Hib disease; therefore, occult invasion of the CNS always must be considered in the context of any manifestation of Hib infection.[147,216] In addition, severe Hib disease often is fatal if not treated adequately. Therefore, elimination of Hib bacteremia and its complications requires antimicrobial therapy that will (1) penetrate the blood-brain barrier to achieve bactericidal concentrations and (2) be of adequate duration to sterilize the primary and potential secondary foci. The choice of specific antibiotic therapy must take into account the local antibiotic susceptibility patterns of invasive isolates (Table 133-3). *H. influenzae* resistance to several antimicrobial agents, including ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, rifampin, and certain second-generation cephalosporins, has been increasing in several areas of the world.[99,183,202,346,420]

For proven or suspected Hib meningitis, cefotaxime or ceftriaxone is recommended until the antibiotic susceptibility of the organism is known or an alternative diagnosis is established.[13,116] Both antibiotics have bactericidal activity against Hib strains, including those that produce β-lactamase, and they penetrate well into infected CSF and are well tolerated. Cefuroxime should not be used for the treatment of *H. influenzae* meningitis because delayed sterilization of CSF may be at least twofold more common than with ampicillin plus chloramphenicol or with the third-generation cephalosporins.[19,394] Moreover, ampicillin, formerly a mainstay of therapy for this infection, should not be used empirically to treat infections caused by Hib because as many as 50 percent of Hib isolates in the United States are resistant, usually via plasmid-mediated β-lactamase production.[202,231] Chloramphenicol, another medication that frequently was used in the past to treat Hib disease,[272,358] now rarely is used because safer antibiotics with greater activity are available. Although adequate bactericidal blood and CNS levels of chloramphenicol can be achieved, even with oral administration,[118,364] its use requires monitoring of drug levels. Dose-dependent, yet reversible, bone marrow toxicity may occur, particularly in neonates, in patients with liver disease, or in those who require prolonged treatment.[272] Idiosyncratic aplastic anemia, a dose-independent complication of chloramphenicol use, is an extremely rare occurrence.

TABLE 133-3 **Selected Antimicrobial Agents for Treatment of *Haemophilus influenzae* Infections**

Antimicrobial Agent	Total Daily Dose (mg/kg)	Dose Frequency
Parenteral*		
Ampicillin†	200-400	Every 4-6 hr
Cefuroxime‡	100-200	Every 8 hr
Cefotaxime	200-225	Every 6-8 hr
Ceftriaxone	50-100	Every 12-24 hr
Oral		
Amoxicillin§	40-90	Three times a day/twice a day
Amoxicillin-clavulanate	40-90	Three times a day/twice a day
Erythromycin-sulfisoxazole§	40 (erythromycin)	Four times a day
Trimethoprim-sulfamethoxazole§	8 (trimethoprim)	Twice a day
Clarithromycin§	15	Twice a day
Azithromycin§	10	Daily
Cefuroxime axetil	30	Twice a day
Cefprozil	30	Twice a day
Cefpodoxime	10	Twice a day
Cefixime	8	Daily
Cefdinir	14	Daily

*Other parenteral agents may be used in special circumstances, but they should not be considered first-line therapy. Such agents include ureidopenicillins, carbapenems, and fluoroquinolones.
†Not to be used presumptively because of the prevalence of resistant strains.
‡Not to be used for suspected meningitis.
§Do not use these oral agents if resistance is suspected or prevalent in your area.

Cefuroxime has good activity against *H. influenzae* and is useful for empirical treatment of nonmeningitic infections such as pneumonia, periorbital cellulitis, and septic arthritis.[431] Other parenteral agents that have activity against *H. influenzae* include meropenem, ampicillin-sulbactam, aztreonam, and other third-generation cephalosporins such as ceftazidime.[231,263] In general, the spectrum of activity of these agents is too broad for routine use in pediatric infections in which Hib is an important pathogen.

Children with occult Hib bacteremia need to be reevaluated carefully because focal disease may develop in 30 to 50 percent of such patients who are clinically well.[84,216] The duration of therapy is determined by the site of infection and the clinical response. Children with uncomplicated Hib meningitis can be treated for 10 days.[13,116] Children with Hib cellulitis can be switched to oral therapy after several days of parenteral therapy, provided that they have had a satisfactory clinical response and do not have meningitis. Patients with septic arthritis should receive at least 10 to 14 days of therapy,[124] whereas children with pericarditis, empyema, or osteomyelitis may require longer courses of antibiotic treatment (3 to 6 weeks).[70,124] These patients often can be switched to oral antibiotics after documenting susceptibility, a good therapeutic response, and adequate antimicrobial blood levels and ensuring compliance.

Equally important in the overall management of a child with invasive Hib disease is supportive care. For Hib meningitis, several studies have shown that adjunctive therapy with dexamethasone moderates the inflammatory cascade and may decrease the likelihood of hearing loss.[310] The recommended dose is 0.6 mg/kg/day given every 6 hours for 4 days, with the first dose administered just before or concurrently with the first antibiotic dose.[13,310,338] Management of a child with meningitis requires continuing careful evaluation for complications such as the development of shock, inappropriate secretion of antidiuretic hormone, seizures, subdural empyema, and secondary foci of infection.[97,98,336] Prolonged fever is a common occurrence, with approximately 10 percent of children remaining febrile for at least 10 days.[116] Repeat lumbar puncture to document sterility of the CSF is not necessary in uncomplicated cases.

In children with epiglottitis, protection of the airway is the most important component of therapy and should be initiated even before the administration of antimicrobial agents.[46] Endotracheal intubation or tracheostomy is performed optimally in the operating room by personnel experienced with these procedures in children. Before establishing the airway, care should be taken not to precipitate laryngospasm by attempting to examine the epiglottis or by performing procedures such as venipuncture.[34,46] Blood should be obtained for culture and intravenous antibiotic therapy initiated as soon as possible after the airway has been secured.

Patients with subdural empyema, pericarditis, or pleural empyema usually require percutaneous or surgical drainage.[70,98] Infected joint fluid should be aspirated from children with septic arthritis to confirm the diagnosis and reduce pressure.[124] Repeated aspirations or placement of a surgical drain also may be needed. Infection of the hip requires surgical incision and drainage to decompress the joint; failure to do so may result in avascular necrosis of the femoral head.[124]

Noninvasive Disease

Noninvasive *H. influenzae* infections, usually caused by nontypeable strains, include otitis media, sinusitis, conjunctivitis, bronchitis, and pneumonia. Numerous orally administered antimicrobial agents are available to treat these infections (see Table 133-3). Despite the increasing prevalence of β-lactamase–producing organisms, amoxicillin remains the drug of choice for empirical treatment of otitis media in most areas because of its low cost and proven safety.[13,239] Several other antimicrobial agents with activity against *H. influenzae* are available and include amoxicillin-clavulanate; trimethoprim-sulfamethoxazole; erythromycin-sulfisoxazole; other macrolides such as clarithromycin and azithromycin; and second- and third-generation cephalosporins such as cefuroxime axetil, cefixime, cefpodoxime, cefdinir, and cefprozil.[231] The quinolone antibiotics, such as ciprofloxacin, also are active but are not recommended routinely for use in children younger than 18 years of age because of a quinolone-induced arthropathy seen in juvenile animals. In the context of poor clinical response or isolation of β-lactamase–producing organisms, amoxicillin-clavulanate, cefixime, and cefpodoxime appear to be the most useful.[13,239]

Most mucosal infections are treated presumptively without obtaining definitive cultures; consequently, the duration of therapy and the need for alternative antibiotics are based on assessment of the clinical response. Otitis media usually is treated for 7 to 10 days, and sinusitis should be treated for at least 1 week beyond the resolution of symptoms.[13,239,436] If resistance is suspected and leads to failure of treatment, an empirical change in antibiotics is indicated.[239]

PREVENTION

The near elimination of invasive Hib disease in the United States and other countries is a direct result of the routine use of Hib conjugate vaccines and represents a remarkable success story.[252] Prevention with hyperimmunoglobulin also has been shown to be effective in high-risk populations, but it is costly, of short-lived benefit, and not licensed for general use.[361] Antimicrobial prophylaxis is effective for the prevention of secondary Hib disease, but it represents only a minor proportion of the overall disease burden.[13,26]

Active Immunization

The first Hib vaccine was the PRP polysaccharide vaccine, which is composed of purified Hib capsular polysaccharide PRP.[20,353] In 1985, in children older than 18 months of age, it became the first vaccine to be licensed for the prevention of Hib disease. Children younger than 18 months of age had inadequate immune responses with PRP vaccination.[17,209] PRP vaccine has immunologic

properties similar to those of some other polysaccharide vaccines, which generally are considered to be T-independent immunogens.[3] As a result, antibody responses are limited and of short duration, particularly in young children, and no booster response occurs with repeated administration of the vaccine. Furthermore, the induced antibody may have reduced functional qualities (i.e., primarily IgM, low avidity).[350,380]

Licensure of PRP vaccine was based on the findings of a large randomized clinical trial conducted in Finland in 1974[320,321] that suggested a protective efficacy of 90 percent for children who were immunized between 18 and 71 months of age. Subsequent to licensure of this vaccine in the United States, it became apparent that routine use of the vaccine resulted in efficacy less than that determined in the Finnish vaccine trial—between 0 and 88 percent.[447] This vaccine is mainly of historic significance because its role has been supplanted by development and licensure of the PRP-protein conjugate vaccines.

Hib conjugate vaccines were developed in an effort to enhance immune responses to the PRP antigen. Basic to all conjugate vaccines is the use of a covalently linked (conjugated) immunogenic protein carrier that confers on the PRP polysaccharide hapten recognition by T cells and macrophages and stimulation of T-dependent immunity.[228,447] Four Hib conjugate vaccines have been developed and evaluated in infants, and all use PRP polysaccharide or oligosaccharides derived from it as the primary immunogen (Table 133-4): PRP-D (diphtheria toxoid), HbOC (mutant diphtheria toxin), PRP-OMP (major outer-membrane protein of *Neisseria meningitidis* serogroup B), and PRP-T (tetanus toxoid). The immune response after administration of Hib conjugate vaccination has the following general characteristics: (1) it is quantitatively enhanced, particularly in younger infants; (2) repeat administration of vaccine elicits booster responses; and (3) maturation of class-specific immunity with a predominance of IgG antibody and probably enhanced functional properties occurs.

The first Hib conjugate vaccine licensed was PRP-D, but it was less immunogenic than are the conjugate vaccines developed subsequently and is not currently used in the United States. In children 15 months of age or older who received PRP-D, high antibody concentrations were achieved with a single dose.[36,189] In infants, however, antibody levels greater than 1 μg/mL developed in less than half, even after receiving three doses.[93,208] Numerous case-control studies have demonstrated that a single dose of vaccine was at least 80 percent efficacious in preventing disease in children 18 months or older. In infants who received vaccine at 3, 4, 6, and 14 to 18 months of age, the protective efficacy after three doses was 94 percent in Finland.[109] In contrast, a trial conducted in Alaska native infants found no evidence of protection in that high-risk population.[444]

A single dose of HbOC is highly immunogenic in children older than 18 months of age,[189,253] and after the administration of three doses in infancy, high antibody levels are achieved.[93,354] Two prospective clinical studies demonstrated that two or three doses of HbOC administered in the first 6 months of life provided a high degree of protective efficacy. In the Kaiser Permanente northern California region population, HbOC was 100 percent efficacious after two doses administered in infancy.[38] The vaccine also was evaluated in Finland in infants who received vaccine at 4, 6, and 14 to 18 months of age, and efficacy was 95 percent after two doses.[110] Data from a third post-licensure study in infants in Los Angeles County also suggested a protective efficacy of 89 percent after two doses and 94 percent after three doses.[429] Although used for a number of years, the HbOC vaccine is no longer available for use in children in the United States.

PRP-OMP induces an immune response that is less age dependent than is the response to the other Hib conjugate vaccines. Adults and children respond to a single vaccine dose with high antibody levels.[354] In infants as young as 6 to 8 weeks, a single dose of PRP-OMP induces a good antibody response.[54] In addition, the antibody levels achieved after two doses are higher than those after two doses of any of the other conjugate vaccines[54,93] and a third dose does not enhance the response. PRP-OMP was evaluated in a randomized, double-blind, placebo-controlled trial involving high-risk Navajo Indian infants[362] who received vaccine at 2 and 4 months of age; an overall efficacy of 95 percent was reported. Additional data from a population-based case-control study in Los Angeles County suggested a level of effectiveness similar to that seen for HbOC.[428]

TABLE 133-4 **Characteristics of *Haemophilus influenzae* Type b Conjugate Vaccines**

Vaccine	Polysaccharide Size	Protein Carrier	Linkage	Trade Name*
PRP-D	Medium	Diphtheria toxoid	Protein with 6-carbon spacer	ProHIBiT
HbOC	Small	CRM_{197} (mutant diphtheria toxin)	PS without a spacer	HibTITER
PRP-OMP	Medium	*Neisseria meningitidis* outer-membrane protein complex	Protein and PS with bigeneric spacer	PedvaxHIB
PRP-T	Large	Tetanus toxoid	PS with 6-carbon spacer	ActHIB
PRP-T	Large	Tetanus toxoid	PS with 6-carbon spacer	Hiberix

*HbOC, PRP-OMP, and PRP-T also are available in combination with diphtheria-tetanus-pertussis, diphtheria-tetanus–acellular pertussis, and hepatitis B vaccines.

HbOC, mutant diphtheria toxin; PRP-D, diphtheria toxoid; PRP-OMP, major outer-membrane protein of *N. meningitidis* serogroup B; PRP-T, tetanus toxoid; PS, polysaccharide.

PRP-T is highly immunogenic in adults and older children,[75,371] and high concentrations of antibody are achieved in infants with a three-dose immunization series at 2, 4, and 6 months of age.[93] The protective efficacy of PRP-T was evaluated in two large prospective randomized trials that were terminated prematurely because of the licensure of other Hib conjugate vaccines for infants. More than 12,000 infants were enrolled in studies in southern California and North Carolina, and no cases of invasive Hib disease occurred in the vaccinated children versus five cases in the control groups.[138,430] Efficacy subsequently was shown in a study in England; after three doses in infancy, the efficacy of PRP-T was estimated to be 100 percent.[45] In Finland, during the first 2 years of its general use, more than 100,000 infants were immunized and only two cases of invasive Hib disease occurred in vaccinees, both after a single dose.

Direct comparisons of Hib conjugate vaccines must be considered in the context of the varying study designs, differences in vaccine lots, and different laboratory and statistical methodologies that were used in the clinical trials. Despite these uncertainties, certain principles are evident: (1) all Hib conjugate vaccines are safe in infants; (2) PRP-D is the least immunogenic conjugate vaccine; (3) only PRP-OMP induces a good immune response after one dose in young infants, but antibody levels are lower than those induced by multiple doses of HbOC and PRP-T vaccine; and (4) PRP-OMP, HbOC, and PRP-T appear to be efficacious, but no direct comparison of the protective efficacy of these vaccines has ever been completed. Mixed administration sequences of Hib vaccines (e.g., PRP-OMP followed by HbOC or PRP-T) may enhance the antibody response,[154,163] and simultaneous or prior receipt of other non-Hib vaccines also may impact the antibody response,[159,161,238] presumably secondary to effects of the carrier proteins. Better understanding of the biologic basis for these observations must await future studies.

Investigation of the feasibility of administering Hib vaccines in combination with other vaccines has been the focus of much research effort over the past decade. Early studies by Schmitt and associates[370] assessed the impact and effectiveness of DTaP (IPV)-Hib combination vaccines in Germany. Although combination DTaP-Hib vaccines elicited lower anti-Hib titers than separate vaccines, the investigators were able to show that combination vaccines were effective in reducing the incidence of Hib disease.[370] Subsequent data from Canada also suggested that a multicomponent Hib-containing combination vaccine was safe and effective in preventing invasive type b *Haemophilus* disease in young children.[365,366] These studies and others led to the subsequent licensing of a five-component combination vaccine (DTaP-IPV-Hib) that has been approved for use in the primary Hib vaccination series for U. S. children since 2008.[68,153]

The phenomenal success of the Hib vaccination strategy has been related to the effectiveness of Hib conjugate vaccines in preventing colonization. Fernandez and associates[121] reported that the anti-Hib capsular polysaccharide antibody concentration required to prevent colonization was greater than that needed for protection against invasive disease. Whether concentrations in the range that Fernandez and associates suggested was important (>5 μg/mL) can be achieved and sustained by using conjugate vaccines in all population groups remains a subject of investigation. Studies in some high-risk population groups (Alaska natives) have documented that invasive disease is prevented best by the use of PRP-OMP Hib vaccine,[392,393] at least for the first dose of vaccine, and that even the use of PRP-OMP Hib vaccine in these individuals may not eliminate carriage of the organism in the population.[95,141] Use of combination vaccines in this population is unlikely to be as effective as use of PRP-OMP Hib conjugate vaccine.[393]

To date, essentially all *H. influenzae* vaccines are based on immunity to the Hib capsule. Antibodies to other components of the bacterium also have been shown to be bactericidal, opsonophagocytic, and protective in animal studies.* Vaccines containing other bacterial antigens could in theory provide supplemental protection against Hib, although this protection does not appear to be necessary in most individuals based on the efficacy of the available Hib conjugate vaccines. Even so, such alternative vaccines could provide immunity to non-Hib strains, which are ubiquitous colonizers of the upper respiratory tract of humans.[113,221] One of the basic problems that must be overcome in the development of such vaccines is the known diversity of many of the candidate vaccine antigens.[30,144] Because of the known strain-to-strain variability in a number of these antigens,[96] finding an antigen relevant to all or most strains has been a challenge.[30,287] Even so, recent human trials have reported success in preventing some cases of *H. influenzae* otitis media with a novel pneumococcal polysaccharide–*H. influenzae* protein D conjugate vaccine[339] and a number of other candidate vaccine antigens remain the subject of active preclinical research.[29,94,222,463,464]

Passive Immunization

Although active immunization clearly is preferred for the control of Hib disease, passive immunization has potential utility in the following settings: (1) selected high-risk groups with a risk for acquiring disease soon after birth and too young to respond to vaccination (i.e., Alaska natives and American Indians), (2) functionally asplenic patients, (3) immunocompromised patients, and (4) prevention of secondary disease in households, daycare centers, or institutions. A human hyperimmunoglobulin from adult Hib-immunized donors called bacterial polysaccharide immunoglobulin has been prepared,[386] but it is not commercially available. Pharmacologic studies show that high levels of antibody can be achieved after intramuscular injection, and significant protective efficacy against invasive Hib disease has been demonstrated in Apache children given three doses during the first year of life.[361] The use of concurrent active immunization with bacterial polysaccharide immunoglobulin also may be an effective strategy.[237] Another possible approach in such groups would be maternal Hib immunization[151] to induce

*References 24, 30, 94, 104, 170, 222, 285, 288, 289, 462.

transplacental antibody, but questions remain regarding the safety and acceptability of vaccinating pregnant women and the inability to immunize women who do not receive prenatal care.

Impact of *H. influenzae* Type b Vaccination

The impact of widespread vaccination with Hib conjugate vaccine has been dramatic and reproduced in many areas of the United States[4,67,252,295] and many other countries throughout the world.[48,127,201,312,322] In general, the decrease in the incidence of disease has exceeded expectations given the estimated proportion of the population completely immunized. In addition, in essentially all these populations, a significant decrease in the incidence of disease was observed in infants before the licensure and recommended use of vaccines in that age group. These findings probably are explained by a reduction in Hib carriage as a result of vaccination[295,410] and, consequently, decreased transmission from immunized children to unimmunized young children and infants.

The immunization schedules vary in different countries to parallel immunization practices for other vaccine-preventable diseases. Also the age-specific incidence of disease varies in different countries. Initially in the United Kingdom the occurrence of disease was such that physicians felt justified to use only a three-dose schedule at 2, 3, and 4 months of age and not to provide a booster dose in the second year of life. As alluded to earlier, this schedule, introduced in the United Kingdom in 1993, appeared to coincide with the reappearance of type b disease in older children observed in the late 1990s.* This experience emphasizes the importance of giving a fourth dose when children are between 12 and 18 months of age.

Chemoprophylaxis

Secondary disease accounts for less than 2 percent of all cases of invasive Hib disease. Chemoprophylaxis, however, can protect susceptible persons from acquiring Hib by eliminating Hib colonization in close contacts. Children younger than 4 years of age have a 600-fold increased risk for acquiring Hib disease after household contact with a case.[445] Risk also appears to be increased in daycare center settings, but this risk is less well defined.[155,314] In addition, adults and older children who are colonized can transmit Hib to susceptible children even though they have little risk for acquiring invasive disease themselves.

Antimicrobial agents effective for chemoprophylaxis must achieve bactericidal levels intracellularly and in mucosal secretions. Rifampin, which achieves high concentrations in respiratory secretions,[266] is the most effective antimicrobial agent for eradicating Hib from the nasopharynx. Rifampin 20 mg/kg once daily (maximal daily dose, 600 mg) for 4 days eradicates Hib carriage in 95 percent or more of household[26,152] or daycare center[158] contacts of a case. Cohort studies have shown the effectiveness of rifampin prophylaxis in preventing secondary Hib disease in household and daycare center attendees.[152,158,255] Antimicrobial agents effective in the treatment of Hib disease, such as ampicillin, trimethoprim-sulfamethoxazole, erythromycin-sulfisoxazole, and cefaclor, have been shown to be ineffective for antimicrobial prophylaxis.[190] However, they eliminated Hib carriage in less than 70 percent of culture-positive contacts and, therefore, are not recommended for chemoprophylaxis.

Both the U.S. Public Health Service Advisory Committee on Immunization Practices[66] and the American Academy of Pediatrics Committee on Infectious Diseases[13] recommend rifampin prophylaxis for all household contacts, including adults, and for the index patient (therapeutic antibiotics do not eradicate Hib from the nasopharynx consistently) if the household has a contact younger than 4 years who is not fully immunized. Prophylaxis should be instituted as soon as possible because the risk for acquiring secondary disease is greatest during the few days after the onset of disease in the index patient and within 2 weeks of the onset of disease. With regard to the daycare center setting, no consensus exists concerning the need for chemoprophylaxis because of uncertainty about the magnitude of the risk for acquiring secondary Hib disease in this setting. Some authors recommend chemoprophylaxis if classroom contacts include those younger than 2 years of age, whereas others think that recommendations should be individualized.[90,314] However, virtually all experts recommend prophylaxis if two or more cases of Hib disease have occurred among attendees within 60 days.[13,66]

In all situations in which the potential for secondary disease exists, this risk should be explained to families, with an emphasis on the importance of seeking prompt medical attention for febrile illnesses. Clinicians should not obtain pharyngeal cultures to determine whether prophylaxis should be administered because doing so only delays the prompt administration of chemoprophylaxis.

CONCLUSION

The perspective on *Haemophilus* disease has changed dramatically in recent years. Before the availability of Hib conjugate vaccines, invasive Hib was one of the most important bacterial pathogens of children. It was the leading cause of bacterial meningitis and an important cause of other bacteremic illnesses. The spectrum of illness is broad, morbidity and mortality are significant, and subtleties in making an early diagnosis and instituting appropriate management exist. Currently, when one considers that most antibiotic use worldwide is for upper respiratory tract infections, including otitis media, and that *H. influenzae* causes a significant proportion of these illnesses, it still must be considered a very important pediatric pathogen.

Although various aspects of disease caused by *H. influenzae* have been reviewed in this chapter, what is clear is that the most important aspect has been disease prevention by routine immunization of infants with

*References 18, 198, 225, 226, 267, 341.

polysaccharide-protein conjugate vaccines. This achievement is the culmination of more than 100 years of research on *H. influenzae*. Although historically there were many technologic problems and misunderstandings about the organism and its pathogenesis, much has been accomplished in recent years. The impact of routine infant immunizations with Hib conjugate vaccines is relatively recent and very dramatic. The public health benefits parallel the eradication of polio and the control of other vaccine-preventable childhood diseases. Widespread Hib immunization virtually has eliminated Hib disease in the United States and in many developed countries where it is used routinely. The degree of disease control exceeded all expectations and is in excess of what the known levels of immunization would have predicted. Unfortunately, Hib conjugate vaccines are currently still not used routinely in many developing countries, and this remains one of the biggest challenges in preventing and eliminating disease worldwide.[277,312]

Some progress has been made at the preclinical level in the development of vaccines against other *H. influenzae* serotypes and nontypeable strains. Control of infection caused by these organisms will have an important public health impact, and the use of such vaccines may have a role in adolescents and adults. The technologies that led to the development of Hib conjugate vaccines served as a prototype for vaccines to prevent disease caused by other encapsulated bacteria including the pneumococcus, meningococcus, and group B streptococcus. As such, the lessons learned in the quest to eliminate Hib disease have had important implications in the control of many other bacterial diseases.

CHAPTER 134

Other *Haemophilus* Species (*ducreyi*, *haemolyticus*, *influenzae* Biogroup *aegyptius*, *parahaemolyticus*, and *parainfluenzae*) and *Aggregatibacter (Haemophilus) aphrophilus*

Stephen J. Barenkamp

Most serious pediatric infections caused by organisms of the *Haemophilus* genus are caused by *H. influenzae*. However, other *Haemophilus* spp. can cause disease occasionally. Among the other species that have been reported to cause disease in pediatric and adolescent patients are *H. aegyptius*, *H. ducreyi*, and *H. parainfluenzae*. *Aggregatibacter aphrophilus*, until recently known as *Haemophilus aphrophilus*, is also an occasional cause of infections in pediatric patients. *H. aegyptius* is currently classified as a member of the species *H. influenzae* (*H. influenzae* biogroup aegyptius), but given the unique characteristics of this organism and the distinctive illness with which it is associated, it will be discussed in this chapter. Other *Haemophilus* spp., such as *H. haemolyticus* and *H. parahaemolyticus*, rarely cause illness in the pediatric population, so they will not be discussed in detail here. Of note, however, *H. haemolyticus* has been the subject recent papers in the literature because nonhemolytic strains of *H. haemolyticus* are sometimes misidentified as *H. influenzae* unless careful and thorough microbiologic testing is performed.[133,144,198]

Members of the *Haemophilus* genus are gram-negative coccobacillary bacteria that are facultatively anaerobic. They demonstrate optimal growth when they are incubated in a humid atmosphere containing 5 to 10 percent carbon dioxide.[105,115,143] Most species have fastidious nutritional requirements and require special media, supplements, or both for optimal growth.[105,115] X factor (hemin), V factor (nicotinamide adenine dinucleotide), or both are required for in vitro growth.[154] Organisms with the "para-" prefix require V factor only. The specific nutritional requirements of *Haemophilus* isolates are one characteristic used to subclassify these organisms into the different species (Table 134-1).

AGGREGATIBACTER (HAEMOPHILUS) APHROPHILUS

Bacteriology

H. aphrophilus was described first by Khairat[104] in 1940 in association with a fatal case of endocarditis. He suggested the species name *aphrophilus* because the organism required relatively high concentrations of carbon dioxide for isolation on the usual media. In earlier times, a well-known manifestation of carbon dioxide was the formation of bubbles of gas in fermenting wine (i.e., froth, or *aphros*).[24,104] Although the organism originally was classified as a *Haemophilus* spp. because of the growth requirement for X factor, more recent studies suggest that it can grow independent of this factor.[105,149,196] Given this latter characteristic and based on other, more recent analyses,[49] the organism has now been placed in the genus *Aggregatibacter* and is known as *A. aphrophilus*.[147,226]

Epidemiology and Pathogenesis

A. aphrophilus is a component of the normal oral flora. Using a selective medium, Kraut and coworkers[108] isolated the organism from gingival scrapings and interdental material of one third of the healthy adults they examined. With respect to disease pathogenesis, it has been suggested that dental disease or manipulation predisposes to transient bacteremia, which results in seeding of distant tissue sites where localized infection subsequently develops.[24,76,146,149,172] In addition, several case reports of patients with *A. aphrophilus* disease reported an association between human infection and contact with or

bites from dogs and cats.[64,93,146,149,209] However, a causal relationship has been difficult to confirm, and the human mouth and respiratory tract probably are the portals of entry for the great majority of infections.

Clinical Manifestations

A. aphrophilus is a relatively rare cause of infection and disease in pediatric patients, with fewer than 50 cases reported in the literature.* Brain abscesses and endocarditis are the pediatric infections reported most commonly.† Other reported sites of infection in children include the oropharynx,[24] the abdominal cavity,[24,102] and various superficial soft tissue sites.[149,216,217] Infections with *A. aphrophilus* do not appear to be associated with any distinctive clinical features in contrast to infection caused by other organisms at the same sites. However, *A. aphrophilus* infections frequently are associated with underlying conditions predisposing the host to infection, such as congenital heart disease, trauma, and immunosuppression.‡

Treatment

Antimicrobial susceptibility testing has not been well standardized for this organism, and disk-diffusion testing, in particular, has been found to be unreliable.[24,88,149,196] Tube or agar dilution testing generally is considered to be the preferred testing method. Older reports found that *A. aphrophilus* was uniformly susceptible to some antibiotics, including chloramphenicol and the aminoglycosides.[24,149,196] Susceptibility to penicillins has been variable. Even so, penicillin has been used successfully for treatment of susceptible organisms,[24,76,149,209] at times in combination with aminoglycosides and other antimicrobials. Some reports document the usefulness of ampicillin or ceftriaxone for treatment of infection.[20,137,146] Several different antibiotics probably can be used to treat *H. aphrophilus* infections successfully. The choice for treatment should be guided by appropriate in vitro susceptibility testing.

HAEMOPHILUS DUCREYI

Bacteriology

In 1889, Ducrey first identified *H. ducreyi* in purulent material recovered from genital ulcers of patients with soft chancre or chancroid.[51] Although unable to culture the organism in vitro, Ducrey was able to establish the specificity of the infectious agent by serial cutaneous inoculations.[51,141] *H. ducreyi* originally was assigned to the *Haemophilus* genus because of its requirement for hemin (X-factor) and a guanosine plus cytosine content within the expected range for *Haemophilus* spp.[8,204] However, more recent studies, including genetic transformation and DNA hybridization analyses, suggest that *H. ducreyi* is not related to the true haemophili, such as *H. influenzae*, and possibly should be placed in a separate genus.[8,204]

The last two decades have seen significant advances in the understanding of bacterial components that contribute to disease pathogenesis. Two cytotoxins, a hemolysin, a diffusible cytolethal distending toxin, and two classes of serum resistance proteins have been identified, their respective genes have been cloned, and their potential contributions to disease pathogenesis have been investigated.* The lipooligosaccharide of *H. ducreyi* has been characterized in much greater detail, and relevant biosynthetic genes have been cloned and studied.† Genes encoding the major outer membrane proteins of the organism have been cloned and the corresponding proteins characterized,[106] and a novel class of pili expressed by *H. ducreyi* has been identified.[34] *H. ducreyi* requires heme for growth and several of the critical molecules required for heme acquisition and use have been identified over the last several years.[54,55,118,192,199] The knowledge gained from molecular characterization of these important bacterial components should enhance efforts to better understand the pathogenesis of disease.

Epidemiology

Chancroid is a genital ulcerative disease found throughout the world. It is seen frequently in Africa, Asia, and

*References 1, 10, 41, 43, 94, 118, 119, 150, 153, 208.
†References 3, 15, 62, 124, 136, 160, 195, 187, 205, 223.

Latin America, where it may be a more common cause of genital ulcer disease than syphilis.[8,21-23,141,202,204] Although generally considered a relatively uncommon cause of illness in the United States, chancroid continues to be diagnosed, particularly in large urban areas among patients, including adolescents, who have genital ulcer disease.* Furthermore, recent data suggest that chancroid may be more common in the United States than suspected because it can be difficult to diagnose correctly using traditional clinical and laboratory means.[50,142,204] Symptomatic disease among patients in the United States has been reported most commonly among nonwhite heterosexual males.[26,65,81,141] However, symptomatic disease is not restricted to men, and female prostitutes have been implicated as important sources of infection in several of the outbreaks reported in the United States.[26,81,141]

H. ducreyi has been the subject of renewed medical and scientific interest since the early 1980s. This interest followed from epidemiologic studies, primarily from Africa, demonstrating that the presence of genital ulcer disease (much of which was chancroid) was strongly associated with an increased risk for heterosexual transmission of HIV infection.† Mechanisms proposed to explain this enhanced transmission included an increased shedding of HIV through the ulcers,[109,204] an increased number of HIV-susceptible cells (e.g., CD4 T lymphocytes) in genital ulcers of a person being exposed to HIV,[188,204] or an increased viral load in the blood and semen of individuals coinfected with HIV and *H. ducreyi*.[53]

Pathogenesis

As noted previously, significant progress has been made over the past 20 years in better understanding the pathogenesis of *H. ducreyi* infection.[4,95,184,204] Several useful in vivo models of *H. ducreyi* infection have been developed. These include a temperature-dependent rabbit model of dermal infection,[161] a primate model of genital chancroid infection in adult pigtailed macaques,[203] a swine model of dermal infection,[90] and an experimental model of human infection.‡ Putative virulence factors have been identified, and their contributions to the pathogenesis of disease are being investigated using several in vitro and in vivo model systems. Some of the molecules and characteristics studied include bacterial lipooligosaccharide,[16,36,124,188,225] pili,§ the cytolethal distending toxin,¶ a hemolysin,‖ serum resistance proteins,[1,41,116,117] lectin binding proteins,[1,97,208,211] and the ability to adhere specifically to epithelial cells of genital origin.[9,114] The contribution of these proposed virulence factors to the pathogenesis of natural infection in humans is still being defined.[95] However, it is known that strains deficient in expression of several of these factors are attenuated in their ability to cause disease in the experimental model of human infection.** Ongoing investigations of *H. ducreyi* undoubtedly will define the virulence mechanisms of the organism more clearly and should enhance efforts to develop protective vaccines.*

Clinical Manifestations

The incubation period of chancroid usually is between 4 and 7 days. It rarely is less than 3 days or more than 10 days.[11,141,170,171] Typically, the first lesion noted is a small inflammatory papule surrounded by a zone of erythema. Within 2 or 3 days, a pustule forms that soon ruptures, leaving a sharply circumscribed ulcer with ragged undermined edges *without* induration.[121,141,170] The base of the ulcer usually has a granular appearance and always is painful. In males, the most common sites of appearance of the ulcers are on the distal prepuce, on the mucosal surface of the prepuce on the frenulum, and in the coronal sulcus. In females, most lesions are at the entrance to the vagina.[121,141,170] Painful, tender inguinal adenopathy is present in up to 50 percent of patients and usually is unilateral. The involved lymph nodes rapidly may become fluctuant and rupture, with the formation of inguinal ulcers.[141,170]

The combination of a painful ulcer with tender inguinal adenopathy is suggestive of chancroid and, when accompanied by suppurative inguinal adenopathy, is almost pathognomonic.[220] However, a significant percentage of patients with *H. ducreyi* infection may have ulcers that can be confused with other genital ulcer diseases, such as herpes or syphilis.[72,121,141,170] Furthermore, as many as 10 percent of patients with chancroid may be coinfected with *Treponema pallidum* or herpes simplex virus.[220] Thus, it becomes mandatory to establish a definitive diagnosis by laboratory means if the diagnosis is to be made with confidence. Recently, chancroid has been described as a cause for chronic lower extremity skin ulcers in children in the South Pacific area,[207] but how common such a presentation may be is unclear.

Diagnosis

As noted earlier, diagnosing chancroid on clinical grounds alone is difficult because the clinical presentation often is not classic and many clinicians do not have a great deal of experience with the disease.[204,220] Definitive diagnosis of chancroid requires isolation of the organism from a genital ulcer or from involved lymph nodes. However, the organism is fastidious and is difficult to isolate, even under the best of circumstances.[141] To obtain specimens for culture, a swab should be used to obtain material from the purulent base of an ulcer or a fluctuant inguinal lymph node should be aspirated directly. Gram stain of purulent material may reveal gram-negative rods in the characteristic "school-of-fish" pattern, but this appearance probably is more characteristic of in vitro propagated organisms.[141] However, even with use of the selective media now recommended for isolation of *H. ducreyi*, it has been estimated that the sensitivity of culture is no higher than 80 percent.[121,220]

Given the low sensitivity of culture, alternative non–culture-based diagnostic tests have been evaluated. Early

studies examined the utility of diagnosing chancroid serologically with an enzyme-linked immunosorbent assay (ELISA) using either an outer-membrane protein preparation or a lipooligosaccharide preparation of *H. ducreyi*.[11] More recent studies have employed slightly altered antigen preparations and serum preparation techniques meant to improve the sensitivity and specificity of the assay.[38] Although these modifications did lead to improvement in the performance characteristics of the assay, the ability of the modified assay to aid in the diagnosis of acute infection remains limited because many patients do not develop a serum antibody response until several weeks after onset of infection.[38,202] Recent work has focused on the use of recombinant proteins as test antigens for a serologic test.[56] This latter assay does appear to show promise for seroprevalence studies, but its utility in the diagnosis of acute infection has yet to be demonstrated. Another recently described diagnostic test relies on detection of *H. ducreyi* with monoclonal antibodies directed against the hemoglobin receptor[155] but it has yet to undergo extensive field testing.

Nucleotide-based diagnostic methods also have been described in recent years.[99,173,204] Perhaps most promising are the polymerase chain reaction (PCR)-based techniques. These assays demonstrate high sensitivity and appear to identify patients with chancroid from whom bacterial cultures for *H. ducreyi* are negative.[202,204] Multiplex PCR assays that can amplify and subsequently detect DNA from *H. ducreyi*, *T. pallidum*, and herpes simplex virus from genital ulcer specimens simultaneously are undergoing field trials and have shown early promise.[129,148,204]

Even if chancroid is diagnosed definitively, it is recommended that patients also be tested for human immunodeficiency virus (HIV) at the time of diagnosis. In addition, it must be remembered that up to 10 percent of patients with chancroid may be coinfected with *T. pallidum* or herpes simplex virus.[220] Appropriate testing for these other pathogens should be strongly considered when a patient presents with any form of genital ulcer disease.

Treatment and Prevention

Successful antimicrobial treatment of genital ulcers caused by *H. ducreyi* cures infection, resolves clinical symptoms, and prevents transmission to others. However, in cases of extensive ulcerative disease, scarring may result, despite successful antimicrobial therapy.[220] The Centers for Disease Control and Prevention (CDC) currently recommends one of four antibiotic regimens for treatment of chancroid in adolescents and adults.[121,178,220] These regimens are (1) azithromycin 1 g orally in a single dose, (2) ceftriaxone 250 mg intramuscularly in a single dose, (3) ciprofloxacin 500 mg orally twice per day for 3 days, or (4) erythromycin base 500 mg orally three times per day for 7 days.[178,220] All four regimens are generally effective for treatment of chancroid among patients without HIV infection.[178] A successful response to therapy usually is apparent within 48 to 72 hours, as shown by decreased ulcer tenderness and pain.[170,178,220] Complete healing of ulcers may take up to 28 days but often is achieved in 7 to 14 days.[170] Healing of fluctuant adenopathy is slower than that of the ulcers and may require needle aspiration through adjacent intact skin or incision and drainage to achieve a successful response to therapy.[59,178]

Patients with HIV infection must be monitored closely because they may require longer courses of antimicrobial agents than the standard regimens just outlined.[178,220] Treatment failures have been noted with several of these regimens,[29,178,206] and some suggestion has been made that persons who are most immunosuppressed are at the greatest risk for failure of standard regimens.[206] Some experts recommend using the erythromycin 7-day regimen for treating all HIV-infected patients because of good experience with this regimen in the HIV-infected population and limited successful experience with the alternative regimens.[178]

It is critical to identify all sexual contacts of infected persons to prevent further spread of *H. ducreyi* disease. The CDC recommends that all persons who have had sexual contact with a patient with proved *H. ducreyi* infection within the 10 days before onset of the patient's symptoms be examined and treated.[220] Contacts should be examined and treated even in the absence of symptoms.

In the longer term, alternative strategies for control of chancroid should be examined. If feasible, vaccination for prevention of *H. ducreyi* infection would be a worthy goal. Data generated in animal models of infection are somewhat encouraging.[2,47,83] Protective immunity to both homologous and heterologous challenge has been reported after immunization of rabbits with cell-surface extracts of *H. ducreyi*.[83] In other work, a purified pilus preparation also was reported to induce immunity in that same model.[47] More recently, immunization with the hemoglobin receptor protein was reported to protect against infection in the swine model of chancroid.[2,71,119] These data suggest that prevention of chancroid by vaccination may be an achievable goal. However, data from the experimental human model of infection suggest that development of a protective vaccine for human use may not be a straightforward process.[6,96]

HAEMOPHILUS INFLUENZAE BIOGROUP AEGYPTIUS *(HAEMOPHILUS AEGYPTIUS)*

Bacteriology

H. influenzae biogroup aegyptius *(H. aegyptius)* was described originally by Koch[107] in 1883 in Egyptian patients with conjunctivitis. A more detailed description of the organism and the clinical characteristics of disease followed 3 years later in the work of Weeks.[214] The Koch-Weeks bacillus has continued to be an important cause of conjunctivitis since these initial reports. Because of several reportedly unique characteristics,[132] the Koch-Weeks bacillus originally was designated as a unique species of the *Haemophilus* genus *(H. aegyptius)* distinct from *H. influenzae*. However, more recent phenotypic and phylogenetic studies, including DNA relatedness

analyses, have raised questions about the validity of this separation.[33,197] The organism is known currently as *H. influenzae* biogroup aegyptius, although debate continues in the literature as to the appropriateness of this designation.[125]

This organism became the subject of intense scientific study in the 1980s as a result of its association with a newly described fulminant and often fatal disease called Brazilian purpuric fever.[31,32] *H. influenzae* biogroup aegyptius was isolated from nine blood cultures and one hemorrhagic cerebrospinal fluid culture collected from 10 clinically ill children in Serrana, São Paulo State, Brazil.[32] The *H. influenzae* biogroup aegyptius strains causing Brazilian purpuric fever were felt initially to be members of a single virulent clone.[33,197] This clone was characterized by the presence of several unique features, including a 24-MDa plasmid with a characteristic restriction endonuclease pattern,[33] a unique multilocus electrophoretic enzyme typing pattern,[145] one of two rRNA gene restriction fragment length polymorphisms,[33,48] a single sodium dodecyl sulfate–polyacrylamide gel electrophoresis profile for whole-cell lysates,[33] specific reactivity with monoclonal antibodies recognizing epitopes unique to Brazilian purpuric fever strains,[120,197] agglutination with antisera specific for the Brazilian purpuric fever clone,[33] and conservation of certain major outer membrane proteins.[167] Although most Brazilian purpuric fever–associated strains of *H. influenzae* biogroup aegyptius appeared to be members of a unique clone, a few Brazilian purpuric fever–associated strains were identified that lacked some of the defining characteristics.[197,200] Furthermore, two cases of Brazilian purpuric fever reported from Australia were associated with strains clearly distinct from the Brazilian purpuric fever clone.[125,197] An excellent review of the epidemiologic, clinical, and laboratory aspects of the disease and its investigation was recently published, and the reader is referred to that work for additional information.[85]

Epidemiology

In the United States, *H. influenzae* biogroup aegyptius has remained an important cause of conjunctivitis, with disease most commonly reported from the southern states.[86] The United States experienced only one reported case of possible Brazilian purpuric fever.[210] In Brazil, the epidemiology of Brazilian purpuric fever became more clearly defined with time.[85,86] The median age of patients with Brazilian purpuric fever was 2 to 3 years, with an overall range of ages of 3 months to 10 years.[31,32] Brazilian purpuric fever appeared to occur with the onset of warmer temperatures and was less likely during the Brazilian winter.[85] Furthermore, it appeared to be more common in small agricultural towns than in larger cities.[31,32,86] Case-control studies attempting to identify risk factors for development of disease identified a history of preceding conjunctivitis as being associated strongly with the development of Brazilian purpuric fever[31,32,86] (although many of the controls also gave a history of conjunctivitis) and suggested that daycare center attendance was an additional risk factor.[32] No additional cases of Brazilian purpuric fever have been reported since the early 1990s. The reasons for the apparent disappearance of the disease remain unclear.[85]

Pathogenesis

Efforts to identify unique virulence factors of *H. influenzae* biogroup aegyptius responsible for the fulminant nature of Brazilian purpuric fever have been ongoing since the initial descriptions of the illness. Progress to date has been limited,[37,85] but recent genome-based studies have demonstrated clear differences between *H. influenzae* biogroup aegyptius prototype strains and other *H. influenza* strains.[123,135,183] Brazilian purpuric fever clone strains express novel or unique surface molecules or secreted proteins that theoretically could result in enhanced virulence.* Distinctive lipooligosaccharide phenotypes,[37,175] IgA proteases,[37,125,134] pili,[15,165,166,218] secreted proteins,[218] and adhesins[180,193] have been reported for Brazilian purpuric fever strains. However, none has been shown to have a specific dominant role in bacterial virulence. One study suggested that the risk for developing Brazilian purpuric fever correlated with the lack of serum bactericidal activity against the Brazilian purpuric fever clone, but this observation needs further confirmation.[174]

Both in vitro and in vivo models were developed for further investigating the pathogenesis of Brazilian purpuric fever.[164,175,215] In these model systems, Brazilian purpuric fever–associated strains demonstrated increased virulence in contrast to control strains not associated with Brazilian purpuric fever, but, again, the specific molecular correlates of this increased pathogenicity have yet to be identified clearly.[164,175]

Clinical Manifestations

The clinical presentation of Brazilian purpuric fever is distinctive and dramatic.[31,32,85,86] The syndrome initially manifests as a purulent conjunctivitis without distinguishing characteristics. Symptoms of Brazilian purpuric fever typically appear 3 to 15 days later, after the conjunctivitis has resolved. The affected children experience the acute onset of fever, which may be associated with vomiting and abdominal pain. Death frequently ensues within 48 hours after the development of disseminated purpura, vascular collapse, and hypotensive shock. The precise pathophysiologic mechanisms responsible for progression from conjunctivitis because of the Brazilian purpuric fever clone to full-blown Brazilian purpuric fever are unknown. The overall case-fatality rate since Brazilian purpuric fever first was recognized is estimated to be 70 percent.[86] Children may develop conjunctivitis with the Brazilian purpuric fever clone and, after recovery from the conjunctivitis, have no further problems.[86] The risk factors that predispose only some children to develop Brazilian purpuric fever are not well understood.

Treatment

Data from the limited number of Brazilian purpuric fever cases studied suggest that early antimicrobial therapy

*References 33, 37, 120, 125, 175, 218.

may improve survival.[32] One suggested regimen is high-dose ampicillin and chloramphenicol. The small number of patients treated to date does not permit a comparison of the efficacy of different antibiotic regimens.[32] Most of the patients who developed Brazilian purpuric fever in the Brazilian studies were treated with topical antimicrobials for conjunctivitis, yet still developed systemic disease.[32] This suggests that local topical therapy is ineffective in eradicating the organism from the host. One study examined the relative efficacy of oral rifampin and topical chloramphenicol in eradicating conjunctival carriage of the Brazilian purpuric fever clone.[157] Although the number of patients who actually carried the Brazilian purpuric fever clone was small, rifampin was shown to be significantly better than topical chloramphenicol in eradicating carriage of the Brazilian purpuric fever clone.

HAEMOPHILUS PARAINFLUENZAE

Bacteriology

H. parainfluenzae was identified first as a species distinct from *H. influenzae* by Rivers[169] in 1922. Both organisms are fastidious, gram-negative coccobacilli, but with in vitro culture, *H. parainfluenzae* can be propagated on nutrient agar plates with supplemental factor V alone (thus the "para-" designation), rather than with both factor X and factor V, which are required by *H. influenzae* isolates (see Table 134-1). Testing for hemolysis on blood-containing media differentiates *H. parainfluenzae* from hemolysis-producing species, such as *H. haemolyticus* and *H. parahaemolyticus*.[105,115] Recovery of *H. parainfluenzae* organisms from blood cultures is enhanced by routine subculturing of all specimens. The organisms tend to grow as small colonies along the side walls of the blood bottles or in the red cell mass, leaving the broth clear. Routine subculturing to supplemented chocolate agar and incubation with supplemental carbon dioxide should allow recovery of any *H. parainfluenzae* organisms that are present.[40,80]

Epidemiology and Pathogenesis

H. parainfluenzae is found commonly in the oropharyngeal flora of normal children.[79,112,128] The organism can be recovered from oropharyngeal cultures of one quarter or more of healthy children. Of children who develop serious invasive disease caused by *H. parainfluenzae*, more than half give histories of identifiable preceding illnesses, such as upper respiratory tract infection, otitis media, or dental infection,[13,25,79,91] suggesting that local inflammation in the upper respiratory tract may predispose to transient bacteremias with this organism, which allows for seeding of other sites, such as the meninges and the heart valves. No specific virulence factors of the organism have been identified to date.

Clinical Manifestations

H. parainfluenzae remains an uncommon cause of infection in pediatric patients, but an increasing number of cases have been reported since the 1970s.[25] The most commonly reported infection is meningitis.* The clinical courses of the patients described with *H. parainfluenzae* meningitis are not remarkably different from those typical of acute bacterial meningitis caused by other organisms. However, the average age of affected children is 2.2 years,[25] an age significantly greater than that of the typical pediatric patient with bacterial meningitis.

The next most commonly reported infection is endocarditis.† *H. parainfluenzae* endocarditis has several unique features. The reported cases of pediatric endocarditis usually occur in adolescents and involve females more commonly than males.[25] The clinical presentation often is subacute and frequently is not associated with localizing signs on physical examination (i.e., pathologic murmurs), at least initially.[40,127,128] Another unique feature of *H. parainfluenzae* endocarditis is the high incidence of major arterial occlusion secondary to release of large emboli from the heart.[25,40,74,127,190] This high incidence of embolization is thought to be due to the particularly friable nature of the vegetations.[25,74] Another characteristic feature noted by several authors is the relatively slow and variable response to antimicrobial therapy of endocarditis caused by this organism.[25,40,127,128]

Other *H. parainfluenzae* infections reported in pediatric patients include brain abscesses,[79,130] septic arthritis,[25] urinary tract infection,[25,84] peritonitis,[131] and sepsis in neonates.[39,168]

TREATMENT

H. parainfluenzae usually is susceptible in vitro to multiple antibiotics, including chloramphenicol, aminoglycosides, trimethoprim-sulfamethoxazole, and third-generation cephalosporins.[25,40,100,128] Although the majority of isolates in the past were susceptible to penicillins, more recent studies have documented an increasing incidence of β-lactamase–producing strains resistant to penicillin and ampicillin.[25,176] For β-lactamase–negative, penicillin-susceptible organisms, administration of ampicillin with an aminoglycoside has been recommended for serious *H. parainfluenzae* infections.[40,82] Individual case reports document successful treatment with a variety of other antimicrobials, including ampicillin alone, cephalosporins, chloramphenicol, and trimethoprim-sulfamethoxazole.[35,40,101,128] At present, pending results of susceptibility testing, it would be reasonable to initiate therapy for serious *H. parainfluenzae* infections with a third-generation cephalosporin, perhaps in combination with an aminoglycoside.

CHAPTER 135

Helicobacter pylori

Aldo Maspons • Mark A. Gilger

The discovery of *Helicobacter pylori* in 1983 as the bacterial cause of peptic ulcer disease[163] revolutionized the understanding, diagnosis, and treatment of acid peptic disease. *H. pylori* appears to infect approximately 50 percent of the world's population, thus rendering it one of the most common bacterial infections in humans.[101,116] An understanding of *H. pylori* is important to pediatricians because this infection usually is acquired in childhood.[88] This chapter details current consensus and understanding of this important pathogen.[46,74,101]

BACKGROUND

The presence of bacteria in the gastric mucosa has been known for more than 100 years.[170] In 1874, Böttcher[18]

observed bacteria in the human stomach. Bizzozero[12] described spirochetes in the stomach of dogs in 1893, and his observations were confirmed by Solomon[175] and by Kasai and Kobayashi[102] in the dog, cat, rat, and monkey. Muhlens[139] and later Luger and Neuberger[120] reported finding spiral organisms in ulcerating carcinomas of the stomach in humans. In 1938, Doenges[39] explored the issue of gastric spirochetes and their clinical relevance. He reported a 43 percent prevalence of spiral organisms in the human stomach in an autopsy review of 242 patients without known gastrointestinal disease. Specimen autolysis, however, rendered interpretation of the pathologic significance of the gastric spirochetes impossible. Freedburg and Barron[66] verified the findings of Doenges in 1940, when they identified spirochetes in the stomachs of 37 percent of patients who had undergone partial gastric resection for carcinoma or ulcer disease. Work on the clinical significance of gastric spiral bacteria continued until a report by Palmer[150] was published in 1954. In an attempt to confirm the findings of spirochetes in the gastric mucosa, Palmer performed an exhaustive review of gastric fundus biopsies from 1000 adult patients, 80 percent of whom were being evaluated for upper gastrointestinal complaints and 20 percent were healthy control volunteers. Palmer noted, "None of the 1180 specimens was found to contain spirochetes or any structure which could reasonably be considered to be of spirochetal nature." He concluded that spirochetes are not part of the human gastric mucosa in health or illness. Palmer, a prominent researcher in gastritis, inadvertently may have curtailed further research into the role of gastric spiral bacteria.

In 1975, Steer,[176] using electron microscopy, noted curved bacteria in stomach biopsy specimens from patients with gastric ulcers. A few years later, Warren, an Australian pathologist, noted the appearance of spiral bacteria overlying inflamed gastric mucosa. Warren noted that this organism looked like a *Campylobacter*. He and Marshall began a series of culture experiments using *Campylobacter*-specific methods. The story culminates in 1983 and 1984, respectively, with their reports of successful culture of the curved bacillus.[2,132] In an attempt to fulfill the remainder of Koch's postulates, Marshall and associates[131] and Morris and Nicholson[138] independently ingested pure cultures of *H. pylori*, and symptomatic acute gastritis developed in both. The organism subsequently was recovered from the gastric mucosa by endoscopy and successfully cultured, thus completing Koch's postulates.

MICROBIOLOGY AND PATHOPHYSIOLOGY

H. pylori initially was named *Campylobacter pyloridis* because of its resemblance to *Campylobacter* spp.[2] and later changed to *Campylobacter pylori*. However, it became clear that the bacterium did not belong to any known genus. An entirely new genus, *Helicobacter*, was created, with *helico* describing the spiral shape and *pylori* denoting its typical location. *H. pylori* is a spiral-shaped, gram-negative bacteria with four to seven unipolar sheathed flagella (Fig. 135-1).[13,148] It is 0.5 μm wide and 3 to 5 μm long and has a smooth surface.[3,136] It generally is "S"-shaped in vivo but can take on many forms, from "U"-shaped to cocci to rodlike.[134]

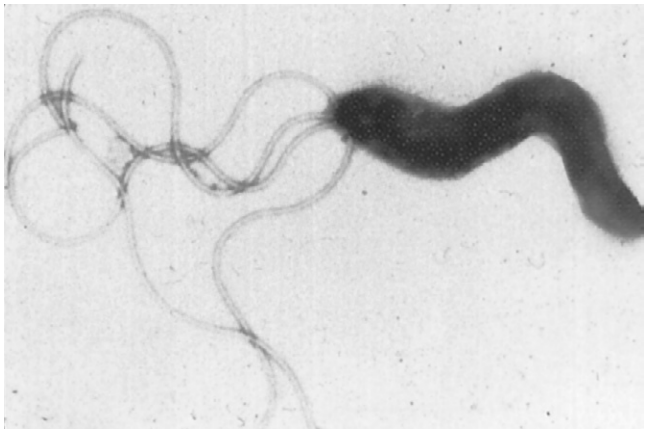

FIGURE 135-1 ■ Electron microscopy of *Helicobacter pylori* demonstrating the multipolar flagella and the typical spiral shape.

H. pylori inhabits a unique ecologic niche—the submucosa of gastric epithelium. Several attributes, including adherence, shape, microaerophilism, urease production, and motility, allow adaptation to the acidic gastric environment. *H. pylori* overlies the intercellular tight junctions of epithelial cells, beneath the mucous layer. Specific adhesion molecules appear to be tropic to gastric mucus-producing cells.[111] This adherence allows the organism to maintain colonization despite the rapid gastric cell turnover.[112] The spiral shape may allow the organism to corkscrew through the gastric mucus (see Fig. 135-1). This spiral movement has been demonstrated in vitro with methylcellulose solutions.[112] *H. pylori* is microaerophilic and grows slowly in culture media.[14,149] Translucent colonies of 1 mm grow after 5 to 7 days on blood-supplemented or serum-supplemented media with a low concentration of oxygen and carbon dioxide at a temperature of 37° C (98.6° F), which promotes optimal growth. This microaerophilism is well suited to the low oxygen levels of the gastric submucosa.[111] *H. pylori* is the most potent urease producer of any known microbe; researchers have estimated that as much as 10 percent of its total protein production is urease, and the organism appears to surround itself in a cloud of ammonia.[3,9,14,151] The urea is converted to ammonium and bicarbonate.[13,76] Little evidence supports the notion that the ammonium produced is cytotoxic to gastric epithelium.[92] The bicarbonate creates an alkaline environment in the gastric submucosa. *H. pylori* produces several other enzymes, including mucinase,[173] lipase,[171] catalase,[117] hemolysin, and cytopathic toxin.[115] The multiple, unipolar flagella (see Fig. 135-1) provide motility that may enable the organism to escape the acid lumen of the stomach[112] and evade host immune responses.[111]

H. pylori may be more akin to normal gastrointestinal flora because the bacterium and the host can coexist for decades without apparent problems.[81] *H. pylori* infection produces inflammation, although in most cases the host is asymptomatic.[16] The inflammatory response is

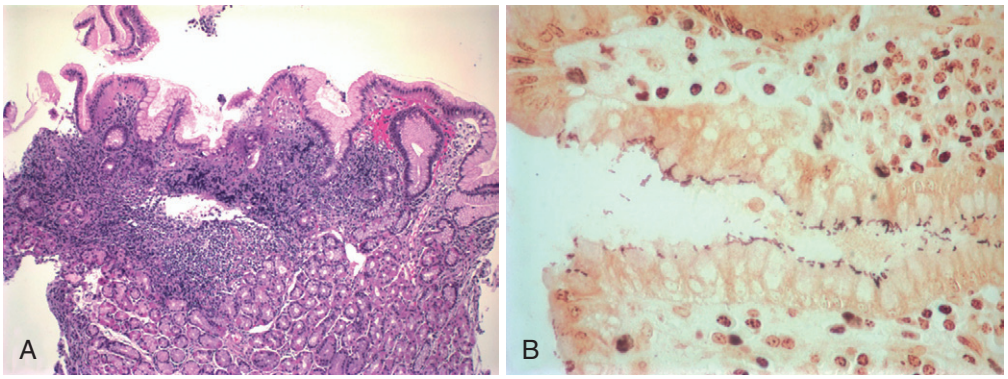

FIGURE 135-2 ■ A, Chronic active gastritis. Corpus mucosa displays a large lymphoid infiltrate (×100, hematoxylin-eosin). **B,** *Helicobacter pylori* are abundant at the surface and line the mucous glands of the gastric pit (×640, silver stain). characterized by infiltration of polymorphonuclear leukocytes, monocytes, lymphocytes, and plasma cells into the lamina propria (Fig. 135-2).[117] A significant immune response, including the production of antibodies, is produced by the host, but it does not clear the organism in most cases.[115] *H. pylori* produces a chronic infection that persists for decades, possibly for life.[117] This lifelong colonization is accomplished by the same features that allow survival in the gastric mucosa, namely, high urease production, flagellar motility, spiral shape, microaerophilism, and adherence.[117]

Numerous potential virulence factors, such as urease, catalase, cytotoxin, and lipopolysaccharide, have been identified, although whether any of these substances actually contribute to symptomatic disease is unknown. The urease of *H. pylori* is a potent antigen that induces elevations in antiurease immunoglobulin (Ig)G and IgA.[117] Interestingly, the ammonia produced by the urease does not appear to have a significant role in pathogenesis.[83] Catalase, another *H. pylori* enzyme, prevents the formation of oxygen metabolites from hydrogen peroxide in neutrophils,[50] which may provide an ability to evade host destruction. A vacuolating cytotoxin has been identified in many *H. pylori* strains,[50] although whether it is more common in patients with symptomatic disease is unclear. *H. pylori* has a peculiar lipopolysaccharide outer membrane. Unlike most gram-negative bacteria, its lipopolysaccharide coat is a significantly less potent inducer of the host complement cascade, some 1000-fold less potent than that of the Enterobacteriaceae.[117] This low biologic activity of the outer membrane of *H. pylori* may be another adaptive mechanism allowing gastric colonization.[15]

The most pathogenic strain of *H. pylori* contains a cytotoxin-associated gene pathogenicity island (Cag PAI).[167,168] The Cag PAI encodes a type IV secretion system with a pilus that directly injects Cag A into the host's cytoplasm. Cag A affects gastric epithelial functions that include cell proliferation, suppression of apoptosis, as well as affecting intercellular junctions.[7] Cag A–positive strains are considered more virulent because of Cag A involvement in the intestinal cell transdifferentiation of gastric epithelial cells—a precursor to carcinogenesis.[141,142]

EPIDEMIOLOGY

H. pylori is one of the most common bacterial infections in humans, with an estimated 1 billion people in the world infected.[101,116] It is estimated that in developing countries more than 80 percent of the population is infected with *H. pylori*, whereas in industrialized countries the infection rate remains under 40 percent (Fig. 135-3).[82,154,155,160,180] Transmission appears to be from person to person.[113,133,182] Transmission via the fecal-oral route is the primary mode of infection.* The presence of pets may be a risk factor for *H. pylori* infection, given that the bacterium has been isolated from domestic animals.[20,21,42,93] Interestingly, breast-feeding appears to increase the risk for acquiring *H. pylori* infection, possibly secondary to close contact with infected mothers, and breast milk does not protect against infection.[41,166,193] *H. pylori* usually is acquired in childhood,[33,116] and humans appear to be a natural reservoir for infection.[85] Environmental sources of *H. pylori* infection, such as municipal water sources, have been confirmed in Peru and Mexico.[119,135]

Children are important factors in the transmission of *H. pylori* infection, which clusters within families with children.[48,126,134,146,189] Family clustering emphasizes the role of crowding and personal hygiene in the person-to-person spread of infection. The prevalence of infection increases with age.[181] In the United States, for example, only about 20 percent of individuals younger than 30 years of age are infected, in contrast to 50 percent of those older than 60 years.[130] Infection in young children is a rare event in the United States and developed nations.[117] The phenomenon of increasing prevalence with age most likely reflects a cohort effect; that is, the high prevalence in older persons simply reflects a higher childhood infection rate.[117] This cohort effect may be explained best by a lower standard of living of older persons during childhood. Socioeconomic status varies inversely with the prevalence of infection, with low-income individuals having the highest rates of infection.[60] Conversely, Ozen and associates[149] found that low

*References 19, 51, 57, 127, 143, 192.

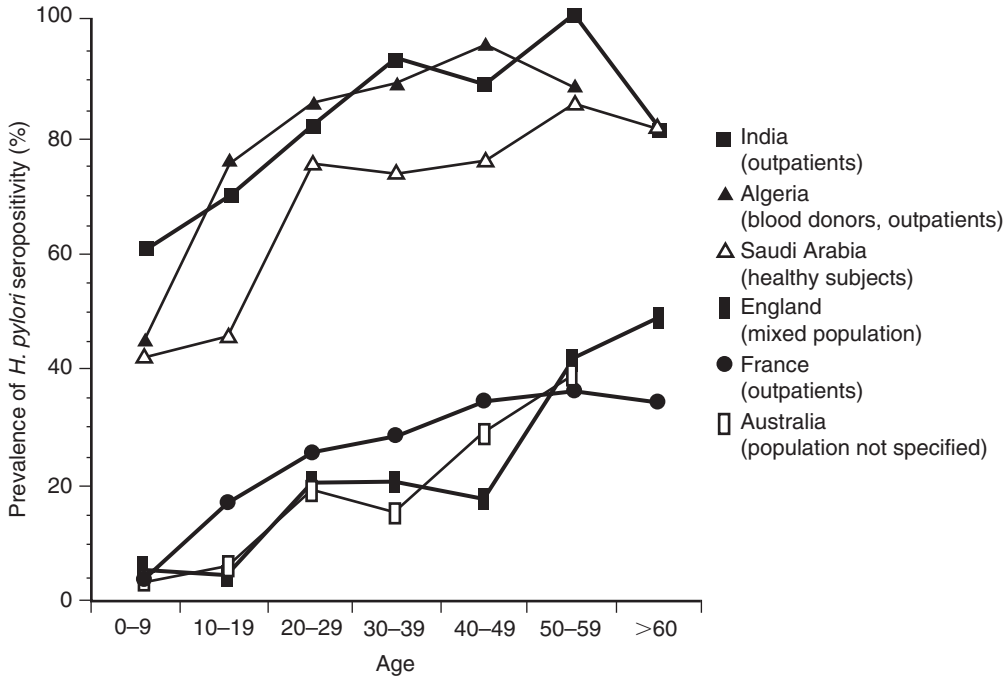

FIGURE 135-3 ■ Seroepidemiology of *Helicobacter pylori* infection demonstrating the difference in disease prevalence between developing and developed countries. (Data from Graham DY, Adam E, Reddy GT, et al. Seroepidemiology of *Helicobacter pylori* infection in India: comparison of developing and developed countries. *Dig Dis Sci* 1991;**36**:1084–8.)

household population and a history of antibiotic use during the previous 6 months served as protective factors against infection. A higher prevalence of infection exists in developing countries than in developed countries (see Fig. 135-3),[134] and the prevalence of infection varies greatly around the world. In Nigeria, for example, 58 percent of children younger than 1 year of age and 91 percent of children older than 10 years were infected.[95] Such differences have been attributed to socioeconomic factors, hygiene, and the number of household occupants.[91] *H. pylori* is more prevalent in blacks and Hispanics than in whites in the United States.[174]

The rate of *H. pylori* reinfection in the pediatric population ranges from 2.4 percent per year to about 20 percent per year.[103,145,146,162,166] Magista and colleagues[125] demonstrated that the difference in reinfection rate depends primarily on the socioeconomic status of the family and the local prevalence of *H. pylori*. They and others[58,59] also noted that living in an area with a high prevalence of *H. pylori* resulted in a fourfold higher risk of reinfection. Although *H. pylori* infection remains common worldwide, the seroprevalence of *H. pylori* infection in U.S. children has dropped significantly in all ethnic groups.[75]

CLINICAL MANIFESTATIONS

Gastritis develops in most *H. pylori*–infected patients, but complications associated with infection develop in only a few.[101] For example, the lifetime risk for developing peptic ulcer disease is estimated to be 10 to 15 percent, whereas gastric cancer will develop in less than 1 percent of *H. pylori*–infected persons.[102] This finding is especially true in children, in whom peptic ulcer is considerably less common than in adults. To confound matters, children have no specific symptoms of *H. pylori* infection.* Symptoms such as epigastric pain, nighttime awakening with abdominal pain, hematemesis, and recurrent vomiting are suggestive but in no way predictive of infection.[47,105,144] Because these clinical symptoms are typical of peptic ulcer disease, testing for *H. pylori* infection alone has no relevance but rather should be done to determine the presence of an underlying condition.[110] Such symptoms possibly are present only if *H. pylori* infection is found with a duodenal ulcer. Furthermore, the presence of *H. pylori* infection alone in both adults and children usually is asymptomatic.†

The association of *H. pylori* infection with recurrent abdominal pain of childhood remains a topic of ongoing debate. The critical issue is whether *H. pylori* antral gastritis is a source of abdominal pain. The issue remains unresolved.‡ A logical conclusion for the pediatrician would be that a child with active upper gastrointestinal tract complaints in whom *H. pylori* infection is suspected deserves either treatment of the infection or diagnostic upper endoscopy to determine the presence of ulcer disease. *H. pylori* infection also has been associated with protein-losing enteropathy, as well as iron deficiency anemia.§ Indeed, successful treatment of *H. pylori* infection improves iron stores.[23]

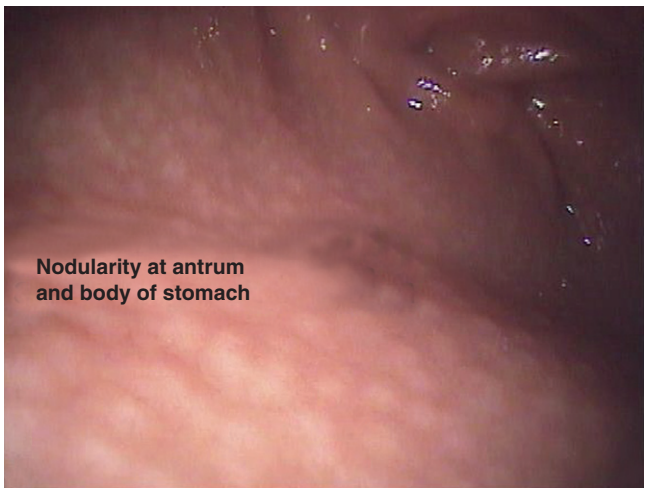

FIGURE 135-4 ■ Endoscopic view of the gastric antrum and body demonstrating marked nodularity of the gastric surface. (See companion Expert Consult website for color version.)

DIAGNOSIS

The gold standard for diagnosis of *H. pylori* infection is culture of the organism from gastric biopsy samples or histologic review.[2] Upper endoscopy or other invasive means are necessary to obtain such biopsy specimens. In children, upper endoscopy can be quite helpful in that it often reveals a distinct nodularity at the antrum (Fig. 135-4), but it also may appear normal. This nodularity is found in two thirds of infected children but only rarely in adults.[22,90,91] Histologically, prominent lymphoid follicles are seen. Routine staining with hematoxylin and eosin may be adequate but must be performed properly to see the bacteria clearly. Alternative staining techniques, such as acridine orange, silver stains, and the "triple" stain, improve visualization.[68,108,124] The triple, or Genta, stain (Steiner hematoxylin-eosin alcian blue) may offer some distinct advantages because it is significantly more sensitive than hematoxylin-eosin staining and is particularly useful for the detection of small numbers of bacteria, which often is the case in children (see Fig. 135-2). Although culture and histology require the need for endoscopy, culture may be important, especially when considering the increase in antibiotic resistance worldwide.[6,37] In cases of recurrent *H. pylori* infection in which antibiotic resistance is suspected, culture allows in vitro antibiotic sensitivities to be determined.

Noninvasive methods for detection of *H. pylori* infection are detailed in Table 135-1 and include serology, varying methods for detection of urease production, detection of salivary antibody, stool culture, stool antigen, polymerase chain reaction (PCR), and urine ammonia production.[158] The 13C-urea breath test is considered the best available noninvasive diagnostic test in children.[53,101] In 2012, it was approved by the U.S. Food and Drug Administration to detect and monitor *H. pylori* infection in pediatric patients 3 to 17 years of age.[53] Serology, on the other hand, is not useful. Measurement of *H. pylori* stool antigen can be performed by either a polyclonal or monoclonal antibody technique.[52,104] This test detects the presence of antigen, thus providing evidence of active infection for both primary diagnosis or proof of cure. It appears to be of equal accuracy to the urea breath test.

H. pylori infection induces a vigorous neutrophilic and lymphocytic (T-cell and B-cell) response that fails to clear the infection. The humoral immune response produces antibodies that can be detected in gastric secretions, as well as systemically. Some *H. pylori* antigens have been determined with the use of bacterial cell wall sonicates, urease, or membrane extracts as the capture antigen.* Some commercial assays have been found to have inappropriate positive and negative cutoff values for use in children.[31,34] Care must be taken to ensure that the serologic tests performed have been verified for use in children. Although detection of IgA, polymeric IgA, and IgM antibodies against haptoglobin can be performed, such detection is not reproducible and thus not of any useful clinical value. Serologic diagnosis, though simple and widely available, does not indicate symptomatic disease.

H. pylori is a vigorous producer of urease. This characteristic has been used to create a variety of tests to detect the presence of urease. The urea breath test uses a labeled carbon of urea, either radioactive carbon-14 (^{14}C)[11] or a nonradioactive, stable isotope, carbon-13 (^{13}C).[84] Patients fast 4 to 8 hours and then drink the labeled carbon accompanied by a meal to delay gastric emptying; then the amount of labeled carbon dioxide in the breath is measured. Only those with gastric *H. pylori* present (and thus gastric urease activity to degrade the labeled urea) will be identified. Urea breath testing is useful for both initial diagnosis and determination of successful treatment because the results rapidly return to normal after eradication. The radioactive ^{14}C method does not deserve consideration for use in children. The stable isotope ^{13}C methodology currently is the simplest and most accurate noninvasive test available method for detection of *H. pylori* infection. Its usefulness remains limited, however, because of the need for specialized equipment for analysis.

The urease production of *H. pylori* can be measured directly in gastric biopsy specimens with a variety of commercial assays.[3,132] A portion of the gastric biopsy specimen is placed into a urea medium, and hydrolysis of urea leads to a color change in the medium from tan to pink. False-negative results have been noted in children because of the low numbers of organisms.[49] Such testing is useful for establishing a rapid diagnosis during endoscopy but requires gastric biopsy. Urease activity also can be detected by measurement of another nonradioactive, stable isotope, ammonium, in the urine after oral ingestion.[100] This noninvasive test has not proved to be accurate. *H. pylori* has been identified in saliva and dental plaque by culture[109] and PCR.[28] Others have identified salivary antibody to *H. pylori* with an indirect immunofluorescence assay.[96] The saliva test is not accurate in young children and cannot be recommended.[70] Viable *H. pylori* organisms have been cultured from feces in Gambian children.

TABLE 135-1 **Summary of Methods for Detecting *Helicobacter Pylori***

Method	Sensitivity (%)	Specificity (%)	Advantages	Disadvantages
Invasive				
Histology	93-99	95-99	Widely available; detection best with special stains; can evaluate underlying mucosal damage; gold standard	Expensive; at least two biopsies required; observer error; recent antibiotics or proton pump inhibitor use can lead to false-negative results
Culture of biopsy specimens	77-92	100	In vitro antibiotic susceptibility can be determined	Expensive; organism requires special transfer and culture technique; requires up to 1 wk for results; recent antibiotics or proton pump inhibitor use can lead to false-negative results
Rapid urease test CLO test hpFast PyloriTek	89-98	93-98	Rapid results; easy to perform; less expensive than other invasive techniques	Formalin, simethicone, local anesthetic spray, recent antibiotics, bismuth, or proton pump inhibitor use can lead to false-negative results; poor technique or handling will affect results
Noninvasive				
Urea breath test ^{13}C ^{14}C	90-100	89-100	Inexpensive, represents entire mucosa (not subject to biopsy sampling bias)	Antibiotics or proton pump inhibitor use can lead to false-negative results; presence of ulcer disease not determined; can be difficult to collect in children younger than 2 yr
Serology (ELISA) HM-CAP Pylori.STAT Rapid serology FlexSure QuickVue	44-99	89-95	Widely available, inexpensive	Not useful after treatment
Stool antigen testing (HpSA)	85-94	97.7	Inexpensive, more accurate than serology; may become the test of choice in children	Stool must be collected
Saliva	71-93	82-92	Easy to collect; inexpensive	Low sensitivity, especially in children younger than 2 yr
Urine (Anti-H. *pylori* IgG antibodies in urine)	90	100	Rapid results, easy to perform, does not require large bacterial load	Length of time needed to prove eradication not known

Data from references 70, 80, 121, 147, 165.
ELISA, Enzyme-linked immunosorbent assay.

TREATMENT

Cure of *H. pylori* infection associated with peptic ulcer disease in both children and adults significantly reduces the likelihood of recurrence of peptic ulceration.[98,130,161,197] The first-line therapy for *H. pylori* infection in children has long been a twice-daily, three-drug regimen that includes amoxicillin, clarithromycin, and a proton pump inhibitor given for 14 days.[25,69,101,185,195] Table 135-2 presents a variety of suggested regimens for the treatment of *H. pylori* infection in children. *H. pylori* infection is difficult to cure.

Confirmation of successful treatment has been defined as absence of detectable organisms by tissue biopsy or the urea breath test at least 1 month after completion of treatment.[10] Because tissue biopsy is invasive, urea breath testing or stool antigen detection is helpful for determination of successful treatment. Serologic tests are not useful for detection of cure because of the prolonged elevation of titers, which remain elevated for 6 months to 1 year or longer after treatment.

A growing body of evidence indicates that acquisition of *H. pylori* infection in childhood is a significant risk factor for the development of gastric cancer such as adenocarcinoma (Fig. 135-5).[97,152,182,187] An estimated twofold to sixfold increased risk for the development of gastric cancer exists among *H. pylori*–infected patients.[45,63,186] A current concern is whether *H. pylori* treatment decreases the risk for development of gastric cancer.[179] Multiple studies have demonstrated that no significant difference exists between treated groups and placebo groups. Patients in whom gastric cancer develops appear to already have atrophic gastritis or metaplasia at baseline.[114,137,194] This finding argues for treatment of *H. pylori* infection in childhood, before the onset of atrophic gastritis. The location of the infection within the stomach may influence the outcome. For example, antral-predominant infection more commonly leads to increased acid secretion, which results in duodenal peptic ulcers and a low risk for gastric cancer. In contrast, fundus-predominant infection leads to decreased acid secretion, which results in atrophic gastritis and a higher risk for gastric cancer.[114] Treatment of gastric lymphoma with antibiotics directed at *H. pylori* has resulted in regression of the tumor.[5,195]

Some researchers argue that the risk for developing either lymphoma or adenocarcinoma provides cause for

TABLE 135-2 **Suggested Treatment Regimens for *Helicobacter Pylori* Infection in Children**

Medications	Dosage	Duration
Triple Therapy		
Amoxicillin	50 mg/kg/day twice daily (maximum, 1 g twice daily)	7-14 days
Clarithromycin	15 mg/kg/day twice daily (maximum, 50 mg)	7-14 days
Proton pump inhibitor* (i.e., omeprazole)	1 mg/kg/day twice daily	7-14 days
Amoxicillin	50 mg/kg/day twice daily (maximum, 1 g twice daily)	7-14 days
Metronidazole	20 mg/kg/day twice daily (maximum, 500 mg twice daily)	7-14 days
Proton pump inhibitor* (i.e., omeprazole)	1 mg/kg/day	7-14 days
Quadruple Therapy		
Bismuth subsalicylate†	15 mL (17.5 mg/mL) four times daily	10-14 days
Metronidazole	20 mg/kg/day twice daily (maximum, 500 mg twice daily)	10-14 days
Tetracycline‡	50 mg/kg/day twice daily (maximum, 1 g twice daily)	10-14 days
Proton pump inhibitor* (i.e., omeprazole)	1 mg/kg/day (maximum, 20 mg twice daily)	10-14 days
Amoxicillin	50 mg/kg/day twice daily (maximum, 1 g twice daily)	10-14 days
Clarithromycin	15 mg/kg/day twice daily (maximum, 500 mg twice daily)	10-14 days
Metronidazole	20 mg/kg/day twice daily (maximum, 500 mg twice daily)	10-14 days
Proton pump inhibitor (i.e., omeprazole)	1 mg/kg/day	10-14 days
Sequential Therapy		
First 5 days		
Amoxicillin	50 mg/kg/day twice daily (maximum, 1 g twice daily)	
Proton pump inhibitor (i.e., omeprazole)	1 mg/kg/day	
Second 5 days		
Clarithromycin	15 mg/kg/day twice daily (maximum, 500 mg twice daily)	
Tinidazole	20 mg/kg/day bid (max, 500 mg bid)	
Proton pump inhibitor (i.e., omeprazole)	1 mg/kg/day	

Modified from Gilger MA. Treatment of *Helicobacter pylori* infection in children. *Curr Pharmaceut Dis* 2000;**6**:370–84; additional data from Gatta L, Vakil N, Leandro G, et al. Sequential therapy or triple therapy for *Helicobacter pylori* infection: systematic review and meta-analysis of randomized controlled trials in adults and children. *Am J Gastroenterol* 2009;**104**:3069–79.

*Comparable proton pump inhibitors such as lansoprazole and rabeprazole can be substituted at appropriate doses.

†Bismuth will produce black stools and has the potential complication of salicylate toxicity. Salicylates also pose the risk for Reye syndrome.

‡Tetracycline is not recommended for children younger than 8 years of age.

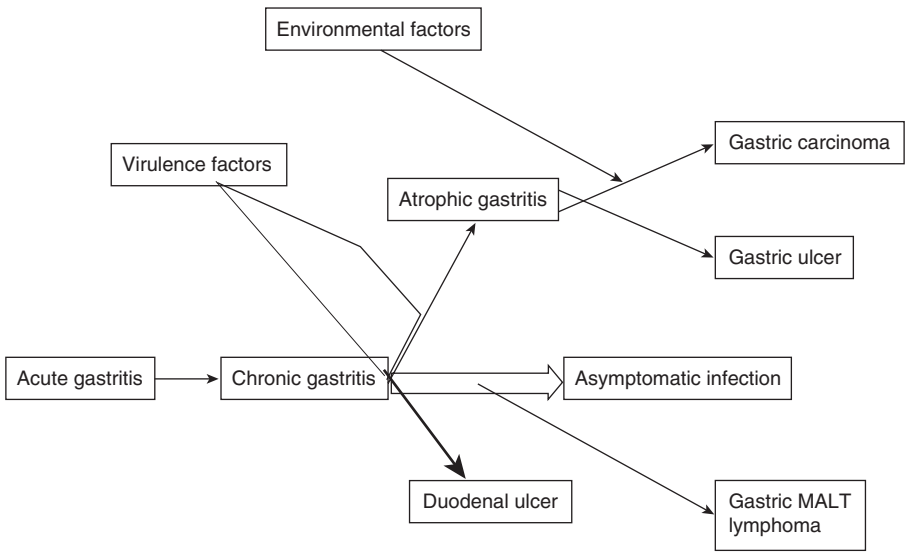

FIGURE 135-5 ■ Timeline of possible outcomes of *Helicobacter pylori* infection starting from the acute acquisition of infection and possible sequelae. *MALT,* Mucosa-associated lymphoid tissue. (Courtesy Dr. D. Graham, personal data.)

the treatment of all children infected with *H. pylori*. Because the risk for development of cancer cannot be predicted accurately and because most children with *H. pylori* infection have no clinical symptoms, no current rationale exists for treating all children infected with *H. pylori*.

In children, the most common anti-*Helicobacter* therapy is legacy triple therapy, which includes amoxicillin, clarithromycin, and a proton pump inhibitor (see Table 135-2).[87,101,129] Resistance to clarithromycin, however, has led to a decline in efficacy from 34 to 66 percent and eradication rates of less than 80 percent.[62,144,189] Eradication rates of greater than 90 percent, however, were demonstrated when *H. pylori* susceptibility testing was performed in children.[4,177] Antimicrobrial evasion to clarithromycin, for example, has been attributed to three point mutations—A2143G, A2142G, and A2142C in domain V of 23S ribosomal RNA.[65,188] Clarithromycin-containing therapy should be used if the area resistance rate is low (<10%),[106] and clarithromycin resistance rates of 15 to 20 percent should dissuade its use. Increasing resistance has prompted newer treatment regimens, such as sequential therapy, which was shown to be superior to legacy triple therapy in treatment-naïve cases, as well as in the clarithromycin-resistant and metronidazole-resistant cases.[65,67,71,99,199] Sequential therapy is 5 days of a proton pump inhibitor and one antibiotic, usually amoxicillin, followed by 5 days of a proton pump inhibitor and two other antibiotics, such as clarithromycin and tinidazole (see Table 135-2).

In patients allergic to penicillin, amoxicillin may be replaced with metronidazole. Metronidazole, to which the *H. pylori* organism has been highly sensitive, has a high rate of resistance because of its overuse for other infections.[54] A multicenter study in Europe found the overall resistance to be 25 percent for metronidazole, 24 percent for clarithromycin, and only 0.6 percent for amoxicillin.[107] In cases of antimicrobial resistance, the use of rifabutin, furazolidone,* and fluoroquinolones, such as ciprofloxacin, along with rifampin and streptomycin, has been reported as options in treating resistant *H. pylori* infection.[43,51,64,169] These second-line regimens have no particular advantage over the first-line antibiotics and should be considered only when resistance is suspected. No single antibiotic agent given alone is effective therapy against *H. pylori*.[130,151,161] Extensive study, including study of antibiotic resistance, should be used to determine the optimal treatment of *H. pylori*.

When cure of infection has been obtained, the long-term rates of reinfection are as low as 1 percent per year in developed countries but much higher in developing nations.[17,153] However, reinfection may be more likely to occur in families, especially when small children are the first infected.[8] Hence, in recurrence, all family members should be tested. No conclusive evidence currently exists, however, to recommend routine treatment of the entire family.[146]

Vaccination against *H. pylori* infection appears possible and also cost effective.[24,44] Vaccination has cleared *H. pylori* infection in animal models.[190] Human models, however, have proved more difficult. The inactivated whole-cell *H. pylori* vaccine failed to eradicate preexisting infection.[118] Although the live-vector, urease-based vaccines did not completely clear all of the preexisting infections, they showed promise and demonstrated a T-cell–mediated response to infection.[1,190] Success in human subjects was demonstrated with an antibody response to aluminium hydroxide–adjuvanted VacA-CagA-NAP vaccine[128] The protease-activated receptor 2 signaling, which is believed to regulate immune and inflammatory responses, has been shown to be important to the vaccine response.[190,191] Despite this progress, the cellular response to bacterial colonization is not completely understood.[140,178] Prophylactic and therapeutic vaccination is needed because current antibiotic therapy does not eradicate *H. pylori* infection in approximately 20 percent of affected patients. Despite vaccination successes in treatment and prevention, the failure to achieve sterilization immunity in animal models has led to continued pathology secondary to *H. pylori*. A truly effective vaccine has thus far remained elusive.[178]

FUTURE DIRECTIONS

H. pylori is a major cause of peptic ulcer disease in children and adults, which has caused a dramatic reappraisal of many previous notions about ulcer disease. Although the dictum "No acid, no ulcer" still holds, many other previous considerations, such as genetic predisposition, must be reexamined. Figure 135-5 demonstrates a proposed *H. pylori* timeline. It emphasizes the acquisition of an acute infection in childhood, persistent chronic gastritis, and the possible progression to ulcer, atrophic gastritis, and, potentially, gastric carcinoma and lymphoma.

As resistance rates of standard therapies for *H. pylori* rise, new therapies are needed. Such novel treatments are represented by benzimidazole derivatives, polycyclic compounds, pyloricidin, aryl thiazole, and plant extracts. New targets for therapy also are being identified. Genes needed for colonization, motility, and urease production, for example, represent such targets.[61]

CHAPTER 136

Kingella kingae

Eric A. Porsch • Kimberly F. Starr • Joseph W. St. Geme III

Kingella kingae is increasingly recognized as an important cause of invasive disease in young children, reflecting improved cultivation methods and new molecular diagnostics for this fastidious organism. Other members of the *Kingella* genus include *K. denitrificans*, *K. oralis*, and *K. potus*. *K. denitrificans* and *K. oralis* are commensals in the human oral cavity and are uncommon pathogens. *K. potus* is a commensal in the oral cavity of arboreal mammals and has been isolated from a wound caused by an animal bite.[33]

HISTORY

K. kingae was first isolated in 1960 from blood, joint fluid, bone exudates, and throat swabs by Elizabeth O. King, a bacteriologist at the Centers for Disease Control and Prevention. King's initial studies suggested that this organism was a novel *Moraxella* sp., prompting shipment of samples to Henriksen and Bovre at the University of Oslo, Norway for their opinion.[21] Work by these investigators confirmed King's initial impressions and led to a

publication describing the new species, which they named *Moraxella kingii* in honor of King.[21] Additional studies in the late 1960s and 1970s established significant differences between *M. kingii* and other members of the *Moraxella* genus and resulted in reclassification as a novel genus and renaming as *Kingella kingae* in 1976.[5,22]

Until the 1990s, *K. kingae* was largely ignored as a human pathogen because of its infrequent recovery in association with disease, generally in young patients with septic arthritis, osteomyelitis, or endocarditis.* As novel culture-based isolation techniques were developed in the early 1990s,[62] the frequency of reported infections caused by *K. kingae* increased. Numerous studies using PCR-based diagnostic techniques have shown that *K. kingae* is present in a significant percentage of culture-negative joint fluid and bone samples from patients with suspected osteoarticular infection.† Recent evidence indicates that *K. kingae* is the leading cause of septic arthritis in children 6 to 36 months of age, more common even than *Staphylococcus aureus*.[14]

MICROBIOLOGY

K. kingae is a gram-negative bacterium that belongs to the *Neisseriaceae* family and is only distantly related to other members of this family. It is a facultative anaerobic, β-hemolytic, small bacillus (0.6 to 1 μm × 1 to 3 μm) that appears as pairs or short chains with tapered ends and often resists decolorization, sometimes resulting in misidentification as a gram-positive organism.[21,55] *K. kingae* produces acid from glucose and maltose but not other sugars and is oxidase-positive and catalase-, urease-, and indole-negative. Growth is supported on blood and chocolate agar but not on Krigler or MacConkey agar. Optimal growth occurs at 37° C (98.6° F) in a 5 to 10 percent carbon dioxide–enhanced atmosphere, but few strains are truly capnophilic.[55] Colonies from growth on solid agar appear as three distinct types: spreading/corroding, nonspreading/noncorroding, and domed.[25,28,55] The spreading/corroding colony type produces marked indentations on the agar surface, develops a peripheral fringe around the small central raised colony, and is associated with high-density piliation. The nonspreading/noncorroding colony has a smaller fringe with a large, flat, central colony and is associated with low-density piliation. The domed colony produces no fringe and is nonpiliated.[28] *K. kingae* is most easily differentiated from *K. denitrificans*, *K. oralis*, *K. potus*, and *Neisseria* spp. by a distinct narrow zone of β-hemolysis surrounding colonies on blood agar plates.

To date, *K. kingae* has never been isolated from a nonhuman source, suggesting that the organism is human specific.

EPIDEMIOLOGY

Carriage and Transmission

K. kingae is a human commensal that colonizes the posterior pharynx asymptomatically in a subset of the population and occasionally invades the bloodstream to produce invasive disease. Using a novel vancomycin-containing medium developed in the early 1990s for isolation of *K. kingae* from the pharynx,[62] several studies examined carriage rates in the healthy population.[10,55,59,63,66] Based on studies conducted primarily in Israel and Europe, colonization with *K. kingae* begins around 6 months of age and increases to a rate of 9 to 12 percent in children 12 to 24 months of age.[10,59,63] The carriage rate gradually decreases in older children and adults, suggesting that immune system development in healthy individuals may be responsible for upper respiratory tract clearance.[59,63]

To achieve a better understanding of the transmission of *K. kingae* strains circulating in the community, pulsefield gel electrophoresis genotyping studies have been performed.[63] In one study, upper respiratory tract isolates from a cohort of healthy individuals were compared to a set of invasive isolates over a 15-year period.[63] Interestingly, this analysis revealed clustering of genotypically indistinguishable strains in geographic regions and households, suggesting person-to-person transmission among family members and close contacts. In addition, many strains circulating among healthy individuals matched historical strains recovered from sites of invasive disease, indicating that certain strains may persist in the population.[63]

In a recent study, Yagupsky and colleagues[64] examined paired isolates from the pharynx and bloodstream in three children with *K. kingae* bacteremia and found that the pharyngeal and blood isolates were genotypically identical in each case, providing evidence that colonization of the posterior pharynx is a precursor to invasive disease. Similarly, Basmaci and associates[1] reported isolation of *K. kingae* from the pharynx in children with confirmed *K. kingae* septic arthritis.

Invasive Disease

The most comprehensive study to date on the epidemiology of invasive disease was a multicenter study in Israel that examined a total of 321 cases of *K. kingae* disease.[17] In this report, 296 of the 312 pediatric cases involved children younger than 4 years of age, representing an annual incidence of 9.4/100,000 children birth to 4 years of age. Of note, only 4 cases involved children younger than 6 months of age.[17] Children younger than 4 years of age diagnosed with *K. kingae* disease were generally otherwise healthy,[17] whereas older children and adults who developed *K. kingae* disease usually had underlying predisposing conditions, including malignancy, immunosuppression, or cardiac valve pathological processes. The 321 total cases included 140 cases of septic arthritis, 19 cases of osteomyelitis, 7 cases of osteomyelitis with septic arthritis of the adjacent joint, and 3 cases of tenosynovitis, for a total 169 skeletal infections (53%/321). Among the remaining cases were 140 cases of bacteremia without a focus (44%/321), 4 cases of with bacteremia and lower respiratory tract infection, and 8 cases of endocarditis.[17] Other reports have described *K. kingae* as a rare etiology of pericarditis,[35] meningitis,[50] peritonitis,[4] urinary tract infection,[40] and ocular infection.[6]

*References 15, 16, 29, 32, 37, 41, 45, 49, 53.
†References 7, 8, 12, 14, 23, 36, 48, 51, 54.

In Israel, invasive *K. kingae* disease occurs throughout the year and is most common during November and December and least common between February and April.[17,18] In contrast, the occurrence of carriage is more uniform throughout the year, suggesting that the seasonal distribution of invasive *K. kingae* disease cannot be readily explained by the epidemiology of pharyngeal carriage. At the time of presentation with *K. kingae* disease, approximately 50 percent of children display symptoms of upper respiratory tract infection, 15 to 20 percent have stomatitis, and 15 to 20 percent have diarrhea, raising the possibility that concomitant viral infection contributes to development of invasive disease.[63]

Daycare Facility Attendance

A longitudinal study in Israel in the mid-1990s aimed to evaluate the transmission of *K. kingae* strains among daycare facility attendees.[47] Fifty isolates were collected over an 11-month period by sampling two cohorts of daycare facility attendees every 2 weeks. These isolates were compared to a collection of 60 epidemiologically diverse respiratory tract and invasive isolates. Based on a variety of typing techniques, children were found to routinely carry the same strain continuously or intermittently for weeks or months. Different strains were able to periodically replace the originally detected strain. Interestingly, a single strain represented 28 percent of the isolates and was most prevalent over the first 6 months of the study and a different strain represented 46 percent of the isolates over the remaining 5 months.[47] Epidemiologically unrelated strains showed much greater variability in relatedness than isolates from the daycare facility cohorts.

To date, three reports of daycare facility outbreaks of invasive *K. kingae* disease have been described.[30,44,60] In Minnesota in 2003, three cases of osteomyelitis/septic arthritis in children from the same classroom of 16- to 24-month olds were diagnosed.[30] Carriage analysis of other attendees of the same facility revealed an overall colonization rate of 13 percent (15/122) and a peak colonization rate of 45 percent (9/20) in the classroom of 16- to 24-month-olds. All three children with invasive disease had concurrent or antecedent upper respiratory tract illness. In Israel in 2005, one confirmed and two suspected cases of *K. kingae* skeletal infections were diagnosed in children from the same daycare facility.[60] Evaluation of the other children at the same facility established that 4/11 were colonized. Pulse-field gel electrophoresis demonstrated that the pharyngeal and invasive isolates from the source daycare facility were genotypically identical and pharyngeal isolates from a control facility where genotypically distinct.[60] Finally, in North Carolina in 2007, a case of confirmed *K. kingae* endocarditis and potential meningitis and a case of suspected intervertebral discitis and osteomyelitis were identified in a 2-week period in children who attended the same daycare facility.[44]

PATHOGENESIS AND IMMUNITY

The pathogenesis of disease caused by *K. kingae* is believed to begin with colonization of the posterior pharynx.[55,65]

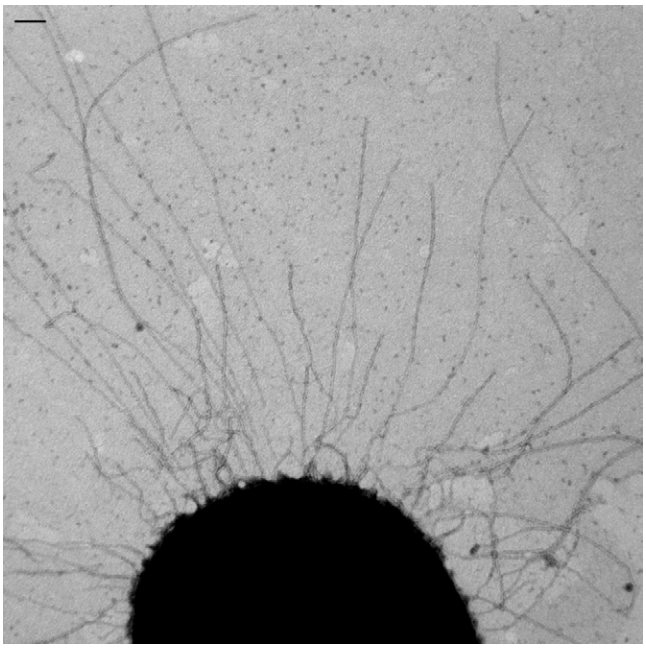

FIGURE 136-1 ■ Transmission electron micrograph of type IV pili emanating from the surface of *K. kingae* strain 269-492, a septic arthritis isolate. The sample was negatively stained with uranyl acetate. Scale bar = 100 nm.

The process of colonization likely involves adherence to respiratory epithelial cells, which is mediated in vitro in part by polymeric surface pili (Fig. 136-1).[26-28] *K. kingae* pili are classified as type IV pili and are composed primarily of a major pilin subunit, PilA1.[26] In addition, *K. kingae* pili contain two pilus-associated proteins, PilC1 and PilC2, that appear to play complementary roles in promoting pilus assembly and in mediating adherence to respiratory epithelial cells.[26] Consistent with the conclusion that pili promote *K. kingae* colonization, examination of a collection of pharyngeal isolates of *K. kingae* demonstrated that the majority are piliated and express abundant pili.[28]

K. kingae also produces a nonpilus adhesive protein, Knh, which is essential for full-level adherence to cultured respiratory epithelial cells.[39] Knh shares homology with the *N. meningitidis* NhhA adhesin and belongs to the trimeric autotransporter family of proteins. Like other trimeric autotransporters, Knh has an N-terminal signal sequence, a characteristic C terminus, and a modular internal passenger domain that is ultimately surface localized. The passenger domain contains a series of 19 YadA-like head domains with similarity to the β-roll that has been implicated in the adhesive activity of the *Yersinia* YadA trimeric autotransporter and a stalk that contains 7 Trp ring domains, 3 neck domains, 3 KG domains, and an iSneck2 domain. Disruption of the gene encoding Knh results in an approximately 50 percent decrease in adherence in in vitro assays.[39]

After colonization of the posterior pharynx, *K. kingae* must translocate across the pharyngeal epithelium to enter the bloodstream. Given that patients with invasive *K. kingae* disease frequently have symptoms of a viral respiratory tract infection, evidence of herpetic gingivostomatitis, or signs of aphthous stomatitis, it is possible

that viral-induced damage to the respiratory mucosa facilitates *K. kingae* invasion of the bloodstream.[55,65] Beyond the role of viral coinfection, *K. kingae* produces a potent extracellular toxin that belongs to the RTX family of toxins and is capable of lysing epithelial, synovial, and macrophage cells.[25] This toxin may facilitate disruption of the respiratory epithelium, perhaps with an increased effect in the setting of viral coinfection. The *K. kingae* RTX locus resembles the RTX locus in *Mycobacterium bovis* and *Neisseria meningitidis* and was likely acquired through horizontal transfer.[25]

Once in the bloodstream, *K. kingae* must be able to evade a variety of host defense mechanisms. Similar to other bacterial pathogens that produce bacteremic disease in children, *K. kingae* produces an extracellular polysaccharide capsule.[2,39] By analogy to other encapsulated bacteria, encapsulation of *K. kingae* may facilitate resistance to serum killing activity and opsonophagocytosis and thereby promote intravascular survival and dissemination to distant sites.[65] At this point, the level of heterogeneity of the polysaccharide capsule among diverse isolates of *K. kingae* remains unclear.

In patients in whom *K. kingae* is able to persist in the bloodstream, the organism may produce uncomplicated bacteremia or instead disseminate to joints, bones, or the endocardium.[55,65] Analysis of a large collection of *K. kingae* systemic isolates demonstrated that strains recovered from the blood of patients with uncomplicated bacteremia were generally piliated but typically expressed relatively few pili.[25] In contrast, strains recovered from joint fluid, bone aspirates, or the blood of patients with endocarditis were generally nonpiliated.[28] It is possible that low-density piliation facilitates a tropism for joints, bones, and the endocardium and potentiates an inflammatory response, which then selects against piliated organisms. Consistent with this possibility, pili promote efficient adherence to cultured synovial cells. Similar to type IV pili expressed by other pathogens, *K. kingae* pili are regulated by a transcription factor called σ54 and by a two-component sensor/regulator system termed PilS/PilR.[27] Mutations in the PilS sensor result in a reduced density of pili, similar to the relative decrease in density of pili in isolates recovered from the bloodstream in contrast to the posterior pharynx. In contrast, mutations in the PilR response regulator result in elimination of piliation, similar to the absence of pili in isolates from joints and bones.[27] It is unclear which environmental factors influence σ54, PilS, and PilR activity and control density of *K. kingae* piliation. The three different colony morphologies that are detectable on agar plates and correlate with the level of piliation may reflect mutations in PilS and PilR.[28]

To investigate the role of the host immune system in development of *K. kingae* disease in healthy individuals, Slonim and colleagues[46] examined serum immunoglobulin (Ig)A and IgG levels against outer membrane proteins in 19 children with invasive disease. As expected, children convalescing from invasive disease had significant increases in IgA and IgG levels. Further analysis has demonstrated that the age incidence of disease is inversely correlated with serum IgA and IgG levels in healthy individuals. Infants younger than 6 months of age have undetectable serum IgA but high serum IgG levels, suggesting that protection from invasive disease in this age group is due to maternally derived IgG.[46] Children between 6 and 18 months of age have the highest age incidence of disease and the lowest serum IgG levels.[17] Children 24 months of age and older have a progressively decreasing incidence of disease and progressively increasing IgG and IgA levels, suggesting that carriage or exposure to *K. kingae* during the first 2 years of life may be an immunizing event. However, *K. kingae* outer membrane protein epitopes are polymorphic from strain to strain, raising the possibility that the immune response is strain specific and may not prevent recolonization by an antigenically distinct strain.[57]

CLINICAL MANIFESTATIONS

Osteoarticular Infections

Septic arthritis caused by *K. kingae* is monoarticular and most often involves the knee, hip, or ankle.[55] Other joints that may be affected include the wrist, shoulder, elbow, sternoclavicular, metacarpophalangeal, and tarsal joints. Fever is present in approximately 85 percent of patients with *K. kingae* arthritis. Arthrocentesis reveals purulent synovial fluid with a mean white blood cell count of approximately 130,000/μL (range ~5000 to ~300,000/μL) and a differential that contains over 90 percent neutrophils.[18] Other laboratory measurements include a mean peripheral white blood cell count of 14,800/mm^3 (range 6000 to 28,450/mm^3), a mean C-reactive protein of 3.7 mg/dL (range, 0.2 to 17.0 mg/dL), and a mean erythrocyte sedimentation rate of 44.1 mm/hr (range, 5 to 140 mm/hr).[17]

Osteomyelitis resulting from *K. kingae* usually involves long bones such as the femur and tibia.[55] However, *K. kingae* also has an unusual predilection to produce disease in small bones, including the calcaneus and talus.[17,55] Children with *K. kingae* osteomyelitis often present with a limp and have a significantly more prolonged course of symptoms before presentation in contrast to patients with septic arthritis (9.2 ± 9.4 vs. 3.2 ± 3.0 days). Laboratory measurements include a mean peripheral white blood cell count of 13,888/mm^3 (range, 5860 to 2,000/mm^3), a mean C-reactive protein of 1.8 mg/dL (range, 0.2 to 4.3 mg/dL), and a mean erythrocyte sedimentation rate of 40.0 mm/hour (range, 12 to 85 mm/hr).[17]

Among patients younger than 4 years of age with spondylodiscitis, at least one quarter have *K. kingae* infection.[9,11,19] In order of frequency, infection involves the lumbar, thoracolumbar, cervical, thoracic, and lumbosacral intervertebral spaces. Patients with *K. kingae* spondylodiscitis usually have a limp, back pain, refusal to sit or walk, or neurologic symptoms. Fever is present in two thirds of patients but rarely exceeds 39°C (102.2°F). Other skeletal infections caused *by K. kingae* include tenosynovitis[55] and dactylitis.[13]

K. kingae bacteremia without evidence of endocarditis or other localizing signs is being increasingly recognized in young children. The duration of symptoms before diagnosis ranges from 1 to 7 days, and the mean maximal

fever is 39°C (102.2°F).[18,55] Occasional patients have a maculopapular rash resembling the rash in early meningococcal or gonococcal infection.[20,49] Laboratory evaluation often reveals an elevated peripheral white blood cell count (mean, 12,700/μL; range, 7120 to 47,040/μL), modest elevation of C-reactive protein (mean, 2.2 mg/dL, range 0.6 to 13.4 mg/dL), and significant elevation of erythrocyte sedimentation rate (mean 50 mm/hr; range, 14 to 115 mm/hr).[17]

K. kingae is included in the HACEK (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella* spp.) group of bacteria accountable for 3 to 5 percent of cases of bacterial endocarditis. In contrast to other *K. kingae* infections, *K. kingae* endocarditis is most common in older children and adults.[55] In approximately 50 percent of cases, infection involves a native valve, often related to a predisposing cardiac malformation or rheumatic heart disease.* Disease usually involves the left side of the heart, most often the mitral valve.[55,65] Patients with *K. kingae* endocarditis typically have fever and elevated C-reactive protein and erythrocyte sedimentation rate.[17] Common complications include congestive heart failure, septic shock, mycotic aneurysm, pulmonary infarction, meningitis, and stroke, and overall mortality is approximately 16 percent.[3,42,44,52,67]

DIAGNOSIS

The recovery of *K. kingae* from purulent specimens seeded onto solid culture media is poor, often resulting in a lack of growth. The yield of cultures is improved significantly by inoculating specimens into Isolator 1.5 microbial tubes or aerobic blood culture vials from a variety of automated blood culture systems such as BacTec, BacT/Alert, and Hemoline DUO.[55] When positive blood culture vials are subcultured onto routine solid media, *K. kingae* grows readily, suggesting that exudates may inhibit growth and that dilution of purulent material in a large volume of broth may decrease the concentration of inhibitory factors, improving the recovery of this fastidious organism.[55] In studies in which blood culture vials were routinely used for culturing synovial fluid aspirates from young children with suspected joint infections, *K. kingae* was isolated in almost half of the patients who ultimately had culture-proved bacterial disease.[36,58]

Studies published over the past decade have demonstrated that polymerase chain reaction (PCR) dramatically enhances detection of *K. kingae* in bone and joint fluid samples in contrast to routine cultures and blood culture vials. Some studies have used universal 16S rRNA primers,[48] and others have used specific primers that amplify either the *K. kingae cpn60* gene or the *K. kingae rtxA* gene.[8,12,23,34] As an example, Chometon and coworkers[14] sequentially analyzed bone and joint samples using blood culture vials, conventional PCR with universal primers, and real-time PCR with primers derived from the *K. kingae cpn60* gene and achieved a detection rate that increased from 29 to 41 to 45 percent of microbiologically proved cases, accounting for approximately 80 percent of cases in children younger than 3 years of age.[14]

Plain radiographs often complement culture and PCR-based diagnostic methods, demonstrating soft tissue swelling and joint effusions in approximately 50 percent of patients with septic arthritis and showing lytic lesions or disk space narrowing in 95 percent of cases of osteomyelitis or spondylodiscitis.[55] Technetium-99m bone scans may be helpful in diagnosing *K. kingae* osteomyelitis during the early course of disease, before abnormalities are present on plain radiographs.[19,20] Echocardiography is helpful in diagnosing *K. kingae* endocarditis and often reveals large vegetations, especially in patients who have had symptoms for a prolonged period or have clinical evidence of embolization.

TREATMENT

K. kingae is typically highly susceptible to penicillins and cephalosporins, although in vitro susceptibility to oxacillin is relatively reduced and β-lactamase production with low-level activity has been reported.[24,31,59] In addition, *K. kingae* is almost always susceptible to aminoglycosides, macrolides, trimethoprim-sulfamethoxazole, tetracyclines, fluoroquinolones and chloramphenicol.[24,31,55,61] Between 40 and 100 percent of isolates are resistant to clindamycin,[61] and virtually all isolates are resistant to trimethoprim and glycopeptide antibiotics, including vancomycin.[18,61]

Given the lack of controlled studies, no detailed guidelines for preferred antibiotic and length of treatment course have been developed for *K. kingae* infections. Typically, treatment varies based on accepted measures for other pathogens. Empiric treatment with intravenous oxacillin/nafcillin or a second-generation or third-generation cephalosporin is appropriate for suspected skeletal infections while laboratory results are pending.[55] In areas where methicillin-resistant *Staphylococcus aureus* is common, addition of vancomycin is recommended.[43] Once *K. kingae* is identified and β-lactam resistance is excluded, antibiotic therapy is commonly changed to amoxicillin or cefuroxime. The switch from intravenous to oral antibiotic therapy should be evaluated based on clinical response and assessment of acute-phase reactants such as C-reactive protein.

Length of antibiotic treatment for *K. kingae* disease has varied based on specific type of infection. Treatment has generally varied from 2 to 3 weeks for *K. kingae* arthritis, from 3 to 6 weeks for *K. kingae* osteomyelitis, and from 3 to 12 weeks for *K. kingae* spondylodiscitis.[55] Patients with septic arthritis usually respond well to antibiotic therapy and do not require repeated joint aspirations or invasive surgical procedures.[55]

Patients with *K. kingae* bacteremia typically have a relatively benign course and are usually treated initially with an intravenous β-lactam antibiotic and then switched to oral therapy once the clinical condition has improved. Antibiotic therapy is generally continued for a total of 1 to 2 weeks.[56]

Children with *K. kingae* native valve endocarditis are usually treated intravenously with a β-lactam alone or in combination with an aminoglycoside.[55] Typically length

*References 3, 38, 42, 52, 55, 67.

of treatment is 4 to 7 weeks.[55] Due to the potential risk for life-threatening valve damage resulting from endocarditis, patients who do not respond to antibiotic therapy may require early surgical intervention.[42,52,67]

PREVENTION

In the three reported cases of daycare outbreaks, oral antibiotics were administered to contacts of the infected children to prevent further spread. The antibiotic courses varied and included either rifampin 10 mg/kg up to 600 mg per dose twice daily for 2 days[30] or a combination of rifampin 20 mg/kg twice daily for 2 days and amoxicillin 80 mg/kg/day for 2 days[44] or 4 days.[60] *K. kingae* carriage was monitored in colonized contacts who received antibiotic prophylaxis. In the first report, 67 percent of colonized contacts became culture negative after prophylaxis.[60] In the second report, 80 percent of colonized individuals became culture negative after prophylaxis.[30] In the third report, carriage rates were low and prevented analysis of colonization at the end of antibiotic treatment.[44]

Currently no measures are available to prevent *K. kingae* infection in the general population. With recent evidence that *K. kingae* expresses a capsular polysaccharide,[2,39] it is possible that a polysaccharide-conjugate vaccine would be a viable approach to prevention of disease, similar to the situation with *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *N. meningitidis*. Further research is necessary to define the heterogeneity of *K. kingae* polysaccharide capsule types and to determine whether selected capsule types are associated with invasive disease and thus represent attractive vaccine antigens.

CHAPTER 137

Legionnaires' Disease, Pontiac Fever, and Related Illnesses

Paul H. Edelstein • Wilbert H. Mason

Legionnaires' disease is an acute pneumonic illness caused by gram-negative bacilli of the genus *Legionella.* Pontiac fever is a febrile, nonpneumonic, systemic illness closely associated with, if not caused by, *Legionella* spp. infection.

HISTORY

Legionnaires' disease (LD) first was recognized as a distinct clinical entity when it caused an epidemic of pneumonia at an American Legion convention in Philadelphia in 1976, where 221 people were affected and 34 died.[74] Investigators were unable to determine the exact cause of the outbreak immediately, and this mystery provoked considerable fear and widespread speculation about the cause. Approximately 6 months later, two investigators at the Centers for Disease Control and Prevention (CDC), Joseph McDade and Charles Shepard, announced that they had discovered the etiologic agent, a fastidious gram-negative bacillus.[128] Researchers determined subsequently that both the organism and the disease had been studied previously as long ago as the 1940s but had been forgotten.[40,57,168] Because of the historical association with the American Legion convention, this disease now is called LD and the etiologic agents belong to the family Legionellaceae.

ETIOLOGIC AGENT

Legionella is the only genus in the family Legionellaceae. More than 50 different species of *Legionella* now are recognized (Table 137-1). The closest pathogenic relative of the Legionellaceae is *Coxiella burnetii*, the agent of Q fever. *Legionella pneumophila* is responsible for the 1976 Philadelphia epidemic and causes most cases of LD.* *L. pneumophila* serogroup 1 is estimated to cause 70 to 90 percent of all cases of LD in previously healthy people.[47,124] *Legionella* spp. other than *L. pneumophila*, and serogroups other than *L. pneumophila* serogroup 1, cause 25 to 40 percent of nosocomial outbreaks of LD; of these *L. pneumophila* serogroups 4 and 6, *Legionella micdadei*, and *Legionella dumoffii* are the most common.[92,185] *L. pneumophila* and *Legionella longbeachae* are the only two *Legionella* spp. that normally infect nonimmunocompromised patients.

The Legionellaceae are obligately aerobic, mesophilic, motile, L-cysteine auxotrophic gram-negative bacilli with variable oxidase and catalase reactions.[56] Genomes of six different *L. pneumophila* serogroup 1 strains have been sequenced, revealing that these bacteria harbor a number of eukaryotic-like genes, a number of secretion systems, remarkable plasticity, and the presence of mobile elements.[79,119] About 10 percent of the approximately 3.5-mb size genome is devoted to strain-specific genes.[20,32,34]

Antigenic relationships among different *Legionella* spp. and among serotypes of the same species are complex.[168] The serologic typing scheme is based on surface antigens (O antigens), which primarily are lipopolysaccharides. These surface antigens are shared by different species and, in rare cases, by other gram-negative bacilli, such as *Pseudomonas* spp. Identifying an unknown strain by use of serologic methods alone occasionally leads to a false or misleading identification. Cross reactions also may be observed in testing for human antibodies to *Legionella* spp. Patients with infections caused by some *Pseudomonas* spp. strains, *Campylobacter jejuni*, and other gram-negative bacilli may develop antibodies to *Legionella* spp.[56]

Identification of *Legionella* spp. other than *L. pneumophila* often requires the capabilities of a research, or national reference, laboratory that performs molecular-based identification.[15] However, isolation and presumptive identification of *L. pneumophila* should be within the capabilities of most clinical laboratories.[56]

Legionella bacteria are ubiquitous in the aqueous environment and can be found, often in high concentrations, in lake water, ponds, bathing water, hot-water tanks, hot-water plumbing, and air-conditioning cooling towers.[168] Optimal growth temperature ranges from 28° C to 40° C (82° F to 104° F). The natural hosts and reservoirs of environmental *Legionella* bacteria are freshwater amebae, such as *Acanthamoeba* and *Hartmannella*.[69] Factors that promote the environmental growth of *Legionella* include the presence of other microorganisms, use of plumbing materials that promote bacterial growth, stagnation, and warm temperatures.[168] In the home, older municipal water distribution systems, use of electric rather than gas water heaters, and use of well water all appear to promote the presence of *Legionella* in water.[69,164] In the particular case of *L. longbeachae*, amebae-laden potting soil exposed to warm temperatures allows multiplication of the bacterium to high concentrations.[181] Most newly discovered *Legionella* spp. have been environmental isolates not associated with clinical illness.[69]

A large number of bacterial virulence factors have been described, the most important of which is the Dot/Icm complex. This complex comprises 26 genes that form a type IV secretion system that is required for *L.*

**L. "jeonii"* is not a validly named species.
†Isolated from humans but unlikely to have caused disease.

pneumophila growth within macrophages. *L. pneumophila* is not killed actively by macrophages. The Dot/Icm complex allows the bacterium to evade normal phagolysosomal trafficking and bacterial destruction, by injecting effectors into the host macrophage within minutes of the time of initial bacterial-macrophage contact. Several hundred injected effectors have been described, but only a few have been fully characterized functionally.[72,97,139] The end result is that the normal host processes are hijacked into providing an intracellular compartment for the bacterium that associates with endoplasmic reticulum.[36,135,154] Other bacterial virulence factors include a variety of enzymes, iron-binding proteins, miscellaneous proteins enhancing intracellular growth, and survival or invasion.[36] An important virulence factor for *L. pneumophila* serogroup 1 is a lipopolysaccharide 8-O-acetylase of unknown pathogenic mechanism of action; bacterial strains with this acetylase constitute the majority of *L. pneumophila* clinical isolates yet are uncommon in the environment.[31]

Availability of intracellular iron appears to play a key role in the growth of intracellular *L. pneumophila*. Interferon-γ, the production of which is increased during *L. pneumophila* infection of macrophages, downregulates the number of iron-binding receptors on macrophages, which has the effect of decreasing the availability of intracellular iron and, hence, limiting intracellular growth of the bacterium.[24]

L. pneumophila is serum resistant.[168] High-titer antibody promotes phagocytosis but may not enhance killing. Macrophage activation factors possibly are more important than is antibody in promoting phagocytosis and bacterial killing.[95]

EPIDEMIOLOGY

Incidence and Frequency

National passive LD surveillance has been initiated through the CDC by using serologic, culture and mainly urine antigen testing. Cases reported to the CDC from 1990 through 2005 included a total of 23,076 cases, of which there were 375 pediatric cases or 1.7 percent of the total number of cases. Most pediatric cases, (44.3%) were in the 15- to 19-year age group, followed by those younger than age 1 year (18.1%).

Pediatric LD rarely appears to be the cause of pneumonia in otherwise healthy children.* Fewer than 15 culture-confirmed cases of LD have been reported in otherwise normally healthy children, and fewer than 70 culture-confirmed cases have been reported in immunosuppressed children.†

A CDC study on the epidemiology of LD in children from 1984 through 2004 found that 66 of 6575 (1%) of cases of LD reported during the period occurred in children younger than 19 years. The median age was 11 years, and 72 percent reported a health care exposure, 30 percent had at least one risk factor for the infection; 26

*References 4, 10, 28, 38, 44, 75, 93, 96, 114, 131, 147, 160, 167.
†References 1, 7, 18, 27, 28, 38, 41, 61, 67, 81, 82, 100, 107, 109, 111, 116, 117, 138, 145, 149, 161, 171, 175, 182.

percent of cases were associated with an outbreak, and 22 percent died.[2] The very low frequency of LD in U.S. children has also been observed in children with pneumonia in Gabon and Germany.[112,180]

A retrospective serosurvey of 500 patients with pneumonia, 83 percent of whom did not need hospitalization, found that only 5 of the 132 patients younger than 15 years of age had significant antibody titers against *L. pneumophila* and none developed seroconversion.[73] The estimated incidence of LD in the overall population was approximately 12 per 100,000 per year. Several prospective serologic studies of children with pneumonia have found that LD constitutes around 1 percent of the diagnosed causes of pneumonia.[38,141,152] This rate is approximately the same as the 0.5 to 4 percent frequency found in the adult population.[40,124,168] LD is not a major cause of pneumonia in either children or adults.

The frequency of LD in immunosuppressed children is unknown, although it is clear that immunosuppressed children can be at high risk for this disease. LD has been reported in children with acute leukemia, chronic granulomatous disease, after bone marrow or solid-organ transplantation, or after being treated with corticosteroids for other reasons.* Nosocomial or community-acquired LD has been reported in several "immunologically normal" infants, who may have had some degree of immunocompromise that predisposed them to this disease.† Neonates appear to be at increased risk for acquiring nosocomial, water-birthing related, and community-acquired LD.[82,117,158,173]

More than 100 cases of Pontiac fever in children have been reported in outbreaks of this disease.[22,78,98,101,120] The risk for acquiring Pontiac fever was found to be greater for younger people in one outbreak,[88,98] which was just the opposite finding of another outbreak investigation.[101] The true frequency of Pontiac fever in children is difficult to know because the diagnosis is impossible to make with certainty in the sporadic form. One hotel hot tub–related outbreak of both LD and Pontiac fever in families and attendees of a youth athletic event found that the median ages of those with LD and Pontiac fever were 6.5 and 15 years, respectively.[22]

Several serosurveys found asymptomatic elevations of *L. pneumophila* antibody in widely varying frequency. In one study, about half of 52 children studied developed an increase in antibody titer unrelated to acute illness over a period of several years.[4] Another study found that 15 percent of 126 children sampled had antibody titers to *L. pneumophila* of 256 or higher, which was not significantly different from those seen with an adult control population.[134] The striking finding was that the antibody titers rose with age, doubling each year until age 3 years, when the values plateaued; this finding held even when patients with pneumonia were excluded. The significance of these elevated antibody titers in children without documented pneumonia is unclear and can be interpreted as cross reactions to other colonizing or infecting bacteria, asymptomatic infection, or atypical disease.

Several investigators have examined the question of whether atypical disease caused by *Legionella* occurs in children using poorly specific serologic tests. Italian physicians found that two children with acute, reversible cerebellar ataxia developed significant antibody titer changes to *L. pneumophila*.[140] Another Italian study found two children with pericarditis who had significant antibody changes.[162] None of 140 British infants with sudden death had measurable antibodies to *L. pneumophila*, despite suggestions that they might be linked.[178] Three studies have shown that children with cystic fibrosis have higher antibody levels to *Legionella* than do normal children, although these data are suspect because of known cross reactions between *Legionella* and *Pseudomonas aeruginosa*.[37,59,104] Thus, despite several epidemiologic surveys, the prevalence of atypical *Legionella* infections in children is unclear.

In adults, LD incidence figures vary widely, most likely related to the insensitivity of passive reporting systems and the vigor of diagnostic testing. The highest reported incidence rates, between 187 to 375 LD cases per million population per year, were reported from a 2008 prospective study of community-acquired pneumonia in Germany, where special efforts were made to capture all cases and to use sensitive diagnostic tests.[176] Significantly lower incidence has been reported in France (20/million/year), where surveillance is passive but disease reporting is mandatory.[26] The reported rate in the United States, 11/million/year, is lower, most likely owing to a reliance on passive surveillance and limited diagnostic testing for the disease.[33] Estimates based on serologic surveys range from 20 to 200 cases per million population per year.[40,150,168] A prospective study in Ohio found that the incidence of LD requiring hospitalization was approximately 60 per million per year, in what is thought to be a geographic region with an above-average frequency of the disease.[125] Estimates of the proportion of adult pneumonias caused by LD range from 1 to 25 percent, with a reasonable mean of 3 percent.[124] Mild or atypical *Legionella* infection certainly occurs in adults, although the exact incidence is unknown. Asymptomatic infection may occur in adults, based on serosurveys. Neither oropharyngeal colonization nor a carrier state has been documented.[19]

LD, although often thought of as an epidemic disease, is actually more common as a sporadic disease. A recent European study showed that sporadic cases represented about 92 percent of all 5960 reported LD cases from 2007 through 2008, similar to the findings in the United States.[33,102]

Risk factors for acquisition of LD can be divided into two main categories: those that increase exposure to contaminated water and those that suppress pulmonary defense mechanisms.[40,168] Included in the former category are occupational or residential exposure to warm or stagnant water, traveling and residence in hotels, and stays in hospitals with contaminated water distribution systems; a risk factor for residential acquisition of disease is use of well water.[164] Weather may be a risk factor in some regions, with increased humidity or rain implicated in a few studies.[71] Included in risk factors that suppress pulmonary defense mechanisms are surgical procedures

requiring general anesthesia, administration of glucocorticosteroids, cigarette smoking, chronic lung disease, and diseases or therapy that compromise the innate or cellular immune systems. Use of biological response modifiers, especially tumor necrosis factor antagonists, is a significant risk factor for LD.[122,172] Alemtuzumab treatment is also a likely significant risk factor for LD. Males are more than twice as likely as females to develop the disease, perhaps as a result of the greater male prevalence of cigarette smoking and chronic lung disease. Middle-aged and older people also are at significantly higher risk than are younger people, as exemplified by recent data from the United States; the incidence rates (per million/year) were 0.2, 0.3, 1.3, 3.6, 8.1, 14.4, and 26.6 for people aged younger than 9, 10 to 19, 20 to 29, 30 to 39, 40 to 49, 50 to 59, and greater than 80 years, respectively.[33] Other than exposure to aerosols of contaminated water, no particular predisposing factors for the development of Pontiac fever have been identified. LD is not contagious and transmission from patients to staff or other patients has never been documented.

Disease Outbreaks

Multiple epidemics of LD and Pontiac fever have been recognized.[18,40,78,168] In the case of LD, most outbreaks have occurred in residents, employees, or visitors to large buildings or in urban settings with exposure to aerosolized water from fountains and cooling towers. Hotels, hospitals, museums, factories, retail stores, office buildings, and housing complexes have all been implicated in LD epidemics. Nosocomial LD has been reported in hospitals throughout the world. Disease reservoirs and disseminators have been potable water distribution systems, air-conditioning cooling towers, hot tub spas, decorative fountains, industrial water systems, and others.[40,168] Outbreaks have been ended by disinfection of water and cooling tower systems by hyperchlorination or pasteurization.[40,168] In some of these outbreaks, disease occurred for many years until effective disinfection procedures were utilized. Attack rates in LD epidemics consistently have been less than 5 percent overall. Incubation periods ranging from 2 to 19 days have been observed, with median incubation periods of 4 to 6 days and average ranges from 2 to 10 days.

Pontiac fever outbreaks generally have been associated with exposure to an aerosol of warm water contaminated with *Legionella*.[77,106,168] Examples include whirlpool baths, an engine assembly plant using contaminated water to cool machine lathes, and a health department building in which condensate in the air-conditioning system was contaminated. The attack rates in Pontiac fever outbreaks have been high, in the range of 95 to 100 percent. The incubation period is short at 12 to 36 hours.[77]

PATHOLOGY, PATHOGENESIS, AND IMMUNITY

Very good, but indirect, epidemiologic and pathologic evidence suggests that LD infection results from inhalation of an aerosol.[40,168] The bacterial form that causes infection is unknown, with possibilities including a sporelike form, intra-amebal bacteria, bacteria enmeshed in biofilm, and bacteria released from biofilm.[69,76,113] Some patients have acquired LD after aspiration of *Legionella*-contaminated tap water, rather than via aerosol inhalation.[16,99,123,174]

In guinea pigs infected by the aerosol route, multiplication of *L. pneumophila* begins within 16 hours.[42] Bacterial multiplication occurs within the alveolar macrophage, although growth in respiratory epithelial cells may also occur. Cell culture studies show that multiplication occurs only in cells and not in the extracellular tissue culture medium.[95] This intracellular location of bacteria protects them from serum factors such as antibody and complement as well as from the effects of those antimicrobial agents that are not concentrated in cells. Killing of *L. pneumophila* within macrophages in cell culture is limited by failure of phagolysosomal acidification and fusion.[95]

L. pneumophila avoids macrophage killing by injecting phagosomal maturation-altering compounds into its host cell within minutes of initial contact using the Dot/Icm type IV secretion system.[97]An additional mechanism involves shedding of bacterial flagellin into the host cytosol, which acts via the innate immune system to alter macrophage killing of the bacteria.[151] In the late phases of bacterial multiplication in macrophages, the bacteria change phenotype to enable infection of the next susceptible macrophage, becoming highly motile, quite small, and more resistant to antimicrobial agents.[8,132] The *L. pneumophila*–containing vacuole becomes huge, occupying almost the entire volume of the macrophage, over a period of a few days. The bacteria effect escape from the presumably nutrient-depleted macrophage by inducing cellular apoptosis and can then infect available uninfected macrophages.[21] Innate macrophage resistance to bacterial infection may be mediated by Toll-like receptors, in particular TLR-2 and TLR-5, and perhaps TLR-4.[88-90] Acquired macrophage resistance to infection derives from activation by interferon-γ and the resultant downregulation of available iron stores.[23] Tumor necrosis factor-α plays a very important role in host defense to infection.[129]

Polymorphonuclear leukocytes neither ingest nor kill the organism effectively in vitro, although animal studies suggest that they may form the bulwark of initial host defenses.[42] Clinical evidence suggests that leukopenic hosts without concomitant macrophage dysfunction are not high-risk candidates for LD, although they may be at higher risk than is the normal population.[29,57]

Lung histopathologic findings in LD show intense intra-alveolar inflammation.[168] Airways larger than the terminal bronchioles are not affected. The interstitial spaces generally are uninvolved, although necrosis of alveoli may bridge the interstitial spaces. The alveoli contain a variable mixture of polymorphonuclear leukocytes, alveolar macrophages, and necrotic debris. Hemorrhage is observed, as are microabscesses. Later, fibrin formation and a histiocytic predominance occur.

Gross lung changes evolve in the classic pattern of lobar pneumonia, with first red and then gray hepatization.[168] Lymph nodes are involved occasionally. The lung

segments involved often are subpleural, a finding that sometimes suggests septic or bland infarction to the clinician. The pleural space is involved variably and seemingly is more prone to infection in immunosuppressed patients. One of the most striking pulmonary findings is the usual absence of significant intrabronchial exudate. This absence of intrabronchial exudate, and lack of bronchial inflammation, may mislead clinicians to exclude bacterial pneumonia.

Despite frequent signs and symptoms of extrapulmonary disease in patients with LD, no specific extrapulmonary pathologic findings have been identified.[168] In fatal cases, organisms often can be recovered or detected in the liver or spleen. Occasionally, patients have nonbacterial endocardial vegetations. Some patients have hilar and paratracheal adenitis. Patients may have metastatic foci with abscesses in almost any location, including the myocardium, pericardium, peritoneum, brain, kidney, bowel wall, perirectal region, prosthetic and native heart valves, muscle and skin, and hemodialysis shunts (Table 137-2).[57,143,168] Bacteremia is rarely detected, although molecular studies and clinical findings suggest that it is common.[57,136,168] Elaboration of toxins by *Legionella* has been postulated to account for some aspects of the systemic disease, but supporting evidence is not convincing.[168]

Host cytokine production in response to *L. pneumophila* infection likely causes most of the acute toxicity of the disease. Cell culture and animal experiments show that tumor necrosis factor, interferon-γ, and other cytokines are produced during *L. pneumophila* infection.[11,183] Humans infected with *L. pneumophila* have been shown to produce a number of cytokines during infection, as well as inflammatory markers such as procalcitonin, neopterin, and C-reactive protein.[43,66,166]

Pontiac Fever (? Toxin-Mediated)

Episodes of recurrent or relapsing LD in patients with elevated antibody titers support experimental evidence suggesting that the humoral immune system plays a minor role in this disease.[57] Also supporting this evidence is the rarity of LD case reports in patients with hypogammaglobulinemia or other diseases in which the humoral immune system primarily is deficient. The rise of specific antibody levels does not seem to have any clinical correlates, nor does the absolute antibody level.[57] Patients may recover from LD without any significant increase in antibody levels, again providing indirect evidence of the limited role of the humoral immune system.

Several studies have shown that passive or active immunization is protective against intraperitoneal and subcutaneous chamber infection in rats, mice, and guinea pigs.[5,60,91,153] Preopsonization of *L. pneumophila* before intratracheal inoculation of hamsters was found to be partially protective, but several investigators have shown that active immunization fails to protect against pneumonia after intratracheal, aerosol, or intranasal inoculation of large numbers of *L. pneumophila* bacteria.[9,48,60] Protective immunity to pulmonary challenge in the guinea pig can be achieved after sublethal infection or infection with an avirulent mutant strain and by vaccination with an *L. pneumophila*–derived metalloprotease or outer-membrane protein.[12-15,179]

Evidence for the importance of the cellular immune system in preventing infection largely is indirect and based on the greater prevalence of LD in immunosuppressed patients with cellular immunodeficiencies.[57,168] Curiously, LD in patients with acquired immunodeficiency syndrome (AIDS) has been reported infrequently, although one epidemiologic survey showed that patients with AIDS had a disease attack rate approximately 40 times greater than that in the normal population.[14,15,124,179]

The pathogenesis of Pontiac fever is not understood. No differences have been detected between an *L. pneumophila* strain isolated from an outbreak of Pontiac fever and strains isolated from outbreaks of LD; these studies have included examination of virulence in an animal model, toxin production, and biochemical characteristics.[168] Detailed clinical studies of patients with Pontiac fever have not been performed, which renders producing an experimental model of this disease difficult. Because it has a short incubation time, which can be as brief as 12 hours, this disease likely does not represent widespread bacterial multiplication within the body, and more likely it represents a toxin-induced or allergic disease. In fact, the link between *Legionella* and Pontiac fever is circumstantial; entirely possible is that other microbes, or their toxins, coexisting with *Legionella* may cause the disease.[77,106] The clinical syndromes most like Pontiac fever are bathwater fever, humidifier fever, and extrinsic allergic alveolitis; these syndromes are thought to be caused either by the direct toxic activity of inhaled endotoxin or by an allergic reaction to microorganisms, most particularly amebae such as *Naegleria* spp.[58,133,156] *L. pneumophila* makes a poorly active endotoxin, suggesting that if inhaled endotoxin is the cause of Pontiac fever then the endotoxin comes from non-*Legionella* bacteria. Support for inhaled endotoxin as the cause of Pontiac fever is found

in two studies of endotoxin present at outbreaks of the disease.[30,70]

CLINICAL MANIFESTATIONS OF LEGIONNAIRES' DISEASE

Signs and Symptoms

Legionnaires' disease usually presents as pneumonia.[57] The pneumonia is atypical in that usual pathogenic bacteria generally are not isolated from respiratory tract secretions or blood and patients do not respond, except fortuitously, to antimicrobial agents commonly used to treat pneumonia in adults (e.g., penicillins, cephalosporins, and aminoglycosides). Beyond this, considerable speculation and controversy continue over whether a distinct clinical syndrome exists. Several prospective studies of both community-acquired and nosocomial LD have failed to demonstrate any clinical, radiographic, or nonspecific laboratory features that distinguish LD from other common causes of pneumonia.[50,65,84] The classic clinical findings are reviewed because many physicians consider that they are distinctive for *Legionella* pneumonias. Whether LD in children mimics the clinical findings in adults is unknown because of the rare instances of well-documented pediatric cases and the possibility of spectrum bias.

The onset of pneumonia may be either insidious or abrupt. Recurrent chills, abdominal pains, myalgia, headache, malaise, anorexia, and severe fatigue are common findings. Diarrhea, consisting of loose, nonbloody stools several times a day, occurs in 30 to 40 percent of cases. Fever may be low grade or absent initially. Over the course of a day to several days, these nonspecific symptoms gradually worsen, often resulting in severe debilitation. These symptoms gradually increase in severity, as measured by the median time of 4 to 5 days to present for hospital care, at which time the patient can be quite ill. Noteworthy is the frequent absence of symptoms referable to the respiratory system. Rash, splenomegaly, adenopathy, and rhinorrhea are exceptionally uncommon findings. Physical examination early in the illness generally is remarkable for a paucity of localizing findings and the frequent impression that the patient has an influenzal or typhoidal illness.

Within a day to several days after onset, the patient usually, but not always, develops high fever. Respiratory complaints, especially dyspnea and pleuritic chest pains, may become prominent. Cough usually is not a major complaint, although it is common. The sputum almost never is frankly purulent; blood-streaked sputum or frank hemoptysis is observed in 20 to 30 percent of patients. Many patients experience confusion, cerebellar ataxia, lethargy, agitation, or some other neurologic disorder. Severe abdominal or back pain may occur, sometimes with localization. Physical examination at this time reveals a "toxic" febrile patient with apparent multisystem disease. Chest examination usually discloses findings of consolidating pneumonia. Depending on the location and stage of consolidation, rales may or may not be heard. Pleural friction rubs or signs of pleural effusion can be observed. Despite frequent symptoms of abdominal pain, signs of peritoneal irritation, such as decreased bowel sounds or rebound tenderness, seldom are detected. Signs of meningeal irritation occur rarely.

Most previously healthy patients recover without specific therapy, usually by day 7 to 10 of illness. Patients with mild disease not requiring hospital admission appear to do quite well without antibiotic therapy.[176] Those who do not recover usually die of progressive respiratory failure, along with failure of other organ systems. Empyema, pulmonary cavitation, renal failure, memory loss, fatigue, and neurologic disorders all are potential complications and may persist for weeks to months after onset of the disease. A variety of extrapulmonary diseases may very rarely occur as the result of LD, most common of which are pancreatitis,[130] hepatitis, and myopericarditis.[6,126] Myositis, as measured by elevated serum creatine kinase levels occurs commonly, with severe muscle disease such as rhabdomyolysis being a rare complication.[105,177] Most of these extrapulmonary diseases improve rapidly with resolution of the pneumonia.

Focal infection without pneumonia is a very rare manifestation of *Legionella* spp. infections, with only a handful of cases reported (Table 137-2). Direct inoculation of bacteria into surgical or traumatic wounds is the usual mode of pathogenesis, although bacteremia and bacteremic metastatic infection have been reported.[127,148] *Legionella* spp. have recently been implicated by polymerase chain reaction (PCR) testing as a cause of persistent cervical lymphadenitis in children, often after hot tub exposure. Because the involved lymph nodes were stain and culture negative for *Legionella* and because the patients failed to improve with macrolide therapy, the study needs verification.[35]

Radiographic Findings

The radiographic hallmark of LD is an acinar filling pattern with consolidation.[40,57,168] There is no distinctive predilection for any lung region; pleural-based consolidation and bilateral infiltrates may occur. Nodular infiltrates may be seen, as may cavitation in the areas of original consolidation. Purely interstitial infiltrates are distinctly uncommon findings in established disease but rarely occur very early in the disease process; these interstitial infiltrates rapidly progress to consolidating ones within a day or so. High-resolution computed tomography (CT) of lungs of patients with LD often reveals a mixture of ground-glass opacities and consolidation, and in the convalescent phase an organizing pneumonia pattern may be seen.[86,184] Pleural effusion, with or without parenchymal infiltrates, is a common finding in chest CT scans and less commonly visualized in plain films. Pleural effusion has been documented as the only chest finding in patients treated early with specific antibiotic therapy.

Laboratory Findings

Nonspecific abnormal laboratory results are common in patients with LD.[40,57] Hematologic abnormalities may include leukocytosis or leukopenia, usually with a left shift; lymphopenia; thrombocytosis; and disseminated

intravascular coagulation. Proteinuria and pyuria are common findings; myoglobinuria also may be present. Hyponatremia and hypophosphatemia commonly occur, as do elevations of aminotransferase enzymes, bilirubin, alkaline phosphatase, lactate dehydrogenase, and creatine kinase. Elevated ferritin is also seen. Severe azotemia occurs, although rarely. Elevation of cold agglutinin titers, cold agglutinin–induced hemolytic anemia, and elevation of complement fixation titers to *Mycoplasma pneumoniae* may also occur. Arterial oxygenation usually is depressed in relation to the extent of pneumonia.

Laboratory diagnosis of LD is best accomplished by urine antigen testing, but this test can be falsely negative. Recovery of *Legionella* from sputum or other lower respiratory tract secretions or tissues requires specialized laboratory testing and is insensitive.[56] Other specific diagnostic methods are detection of *L. pneumophila* antigen by immunofluorescent microscopy and detection of *Legionella* DNA in respiratory tract specimens using the PCR assay. Serologic diagnosis is of uncertain value in children, but it is useful in adults.

Sputum is plated on buffered charcoal yeast extract medium supplemented with α-ketoglutaric acid (BCYE-α) and on BCYE-α supplemented with antibiotics.[56] *Legionella* organisms grow on these media 3 to 7 days after inoculation and incubation at 35° C in air. Culture diagnosis has a higher yield than does immunofluorescent microscopy or serology and yields no false-positive results. Sputum culture yield depends on the severity of illness; it is close to 100 percent for LD affecting immunocompromised patients and patients with ventilator-dependent pneumonia but can be as low as 10 to 25 percent in mild LD. Blood and pleural fluid cultures have very low yield, less than 5 to 10 percent, with blood culture only positive in severely ill, usually immunocompromised, patients.

Immunofluorescent microscopy for *L. pneumophila* is a rapid and highly specific (99.9%), but insensitive (50% to 70% sensitivity), technique for diagnosis.[56] It can be performed on sputum or lung tissue in 1 to 2 hours after receipt of the specimen. The test is technically demanding, requiring extensive expertise and training; use of the test by inexperienced technologists yields more false- than true-positive findings. Because of these difficulties few laboratories perform this testing.

Serologic testing is of most value in epidemiologic studies and of least value in the acute diagnosis of sporadic cases.[54] As many as 25 percent of patients with culture-documented disease fail to undergo seroconversion against the homologous serotype; this failure is not related solely to early treatment or immunosuppression, although these factors may cause failure of antibody formation. As long as 3 months may be required for antibody levels to increase after onset of illness; the median time is approximately 2 weeks. Also, as with any other means of immunologic diagnosis of this disease, the multiplicity of antigenic types renders serologic testing extremely cumbersome. Because between 5 and more than 25 percent of the normal population have antibody titers as high as 1:512 to *Legionella*, only a fourfold rise in titer is considered significant. The specificity is highest for *L. pneumophila* serogroup 1 and much lower for other species. Commercial testing kits can yield false-positive results and may also be insensitive in comparison to reference laboratory tests. Only paired samples, drawn 3 to 6 weeks apart, and tested in parallel, should be tested. Specimens taken up to 9 to 12 weeks after onset of the disease should be tested if earlier samples reveal no changes. A negative serologic result does not exclude disease.

The specificity of seroconversion to *L. pneumophila* serogroup 1 ranges from 95 to 99 percent.[54] Cross-reactive antibodies may be found in the serum of patients with leptospirosis, melioidosis, *Bacteroides fragilis* infections, *P. aeruginosa* infections, *C. jejuni* enteritis, and possibly *Haemophilus influenzae* or enteric bacterial infections. However, even 99 percent specificity is not sufficient for certainty of diagnosis of a sporadic case. If the estimated 1 percent prevalence of LD in children is correct, fewer than 50 percent of all seroconversions yield truly positive results (positive predictive accuracy of 45%). This observation, combined with the studies cited previously showing age-related elevations of anti-*Legionella* antibody in young asymptomatic children, renders serologic diagnosis of pediatric LD highly suspect.

Detection of soluble bacterial antigen in urine can be used to diagnose *L. pneumophila* serogroup 1 infections successfully and is the most sensitive and most rapid test for community-acquired LD.[53,56] The major drawback of this test is that it preferentially detects only *L. pneumophila* serogroup 1 infections. Otherwise, it has an excellent sensitivity (90% to 99% vs. culture and 60% to 70% in patients with community-acquired LD) and extraordinary specificity (at least 99.9%). The antigen test may be positive when sputum culture for *L. pneumophila* serogroup 1 is negative, especially in previously treated patients and in epidemics of LD. In nosocomial LD, and in LD of immunocompromised patients the antigen test is less sensitive, because other serogroups and other *Legionella* spp. become likely in these groups. Although the antigen test detects 60 to 70 percent of those with community-acquired LD, fewer than 40 percent of patients with nosocomial cases test positive. A negative urine antigen test should not be used as the sole reason to stop therapy for LD.[49]

The PCR test has been used to detect *L. pneumophila* in sputum, serum, and urine. Whereas both sensitive and specific PCR tests are available, none is commercially available in the United States. Several U.S. reference laboratories perform home-brew PCR assays. PCR testing appears to add about 11 percent additional yield to that obtained by urine antigen testing and may not be cost effective.[46]

With the exception of the urine antigen test, none of the nonculture tests is as sensitive as is culture diagnosis. Culture should be performed in every case; if desired, the other tests can be used to provide same day answers. Because none of the *Legionella*-specific tests is 100 percent sensitive, the clinician sometimes must treat for LD in the absence of confirmatory laboratory tests. One or 2 days of therapy with erythromycin apparently does not affect the sensitivity of the diagnostic tests, although therapy with azithromycin or levofloxacin can affect culture yield. Therapy should not be withheld pending results of laboratory tests.

TREATMENT

No adequately sized prospective clinical studies of antimicrobial therapy for LD have been performed. All recommendations regarding therapy are based on retrospective and small prospective clinical studies, as well as laboratory studies.

Because of the superiority of newer fluoroquinolone agents and azithromycin in experimental nonhuman studies, and on the basis of uncontrolled trials of these agents in adults with LD, the current recommendation is that adults with severe LD and immunocompromised patients with the disease be given either azithromycin or fluoroquinolone therapy, rather than erythromycin or clarithromycin therapy. In one prospective observational study in adults that compared levofloxacin-treated patients with those who received the less-effective macrolides, erythromycin and clarithromycin, those who received levofloxacin had a significantly shorter time to defervescence and a shorter length of hospital stay than those treated with erythromycin or clarithromycin.[137] However, other studies have shown no significant differences in outcome for patients treated with clarithromycin or levofloxacin.[63,83] Nonhospitalized patients with mild LD can be treated equally well with any of the specific therapies, including doxycycline, newer fluoroquinolones, azithromycin, clarithromycin, or erythromycin.[51,52,121] No inherent reason, other than age-specific drug toxicity, precludes these guidelines for children.

Fluoroquinolone antimicrobial agents generally are contraindicated in children, although the evidence suggests that the risk for toxicity from short courses of therapy is low. The scope of this chapter does not allow the discussion of the use of these drugs in children, but in some cases the benefit of using these drugs in severe LD may be greater than the potential risk for development of drug side effects.

Clarithromycin 7.5 mg/kg every 12 hours may be used in place of erythromycin, although there are good laboratory and reasonable clinical data showing that this drug is no more effective for LD than is erythromycin.[17,144] Clarithromycin is not FDA approved for the treatment of LD. Azithromycin has largely replaced erythromycin as the drug of choice for the treatment of LD in children, primarily because of the adverse effects associated with erythromycin, especially gastrointestinal effects and severe phlebitis when given intravenously.

Azithromycin, which is approved for use in children in the United States, is as active against *Legionella* bacteria as are the newer fluoroquinolone agents, making it a candidate for the drug of choice for severe pediatric LD or for LD in immunocompromised children. The drug dose for children for this type of pneumonia has not been studied, but based on extrapolation from adults, a dose of 10 mg/kg (maximum, 500 mg) given once daily for 3 to 5 days should be sufficient in most cases, with extended duration of therapy (7 to 10 days) for severely immunocompromised patients. Azithromycin is available in both intravenous and oral forms and is approved by the FDA for use in adults with LD.

Newer fluoroquinolone agents, along with azithromycin, are considered to be the drugs of choice for the treatment of severe LD in adults. Levofloxacin is used commonly in the United States to treat this disease, in a dosage of 500 mg daily for 10 to 14 days. No dosage guidelines exist for the treatment of pediatric LD because of the potential for drug toxicity in this population. Levofloxacin is the only available quinolone agent approved by the FDA for the treatment of LD in adults; note that neither ciprofloxacin nor moxifloxacin is approved for this indication. Ciprofloxacin appears to be effective for this indication on the basis of case reports, and moxifloxacin may be effective based on limited laboratory studies. Combining azithromycin with levofloxacin has been reported to be more effective than levofloxacin alone in a very small inadequately controlled study; until this is confirmed in larger studies, use of this combination should be avoided.[36]

Alternative drugs to macrolides or quinolones include doxycycline and possibly co-trimoxazole. Neither of these agents has been approved for this use by the FDA, although limited clinical and experimental data support their effectiveness, more so for doxycycline than for co-trimoxazole. Co-trimoxazole should only be used if there is no possibility of using a macrolide, tetracycline, or fluoroquinolone drug. Doxycycline, because of its high lipid solubility, may be more effective than is tetracycline, although whether this is true remains conjecture. The dosage of doxycycline used in children is 2 to 4 mg/kg/day, given in one or two doses. Use of tetracyclines is associated with the risk for dental staining in children younger than 8 years of age. The daily co-trimoxazole dosage is 15 to 20 mg/kg of the trimethoprim component and 75 to 100 mg/kg of the sulfamethoxazole component in three divided doses; cotrimoxazole use in newborns may cause kernicterus. Duration of therapy for these drugs is the same as that for erythromycin.

Rifampin combined with erythromycin is a less favorable alternative to the use of azithromycin by itself. However, if erythromycin is a preferred therapy for reasons of cost, toxicity, or availability, then rifampin probably should be added in the case of severe disease or in immunocompromised patients. The dosage is 16 to 20 mg/kg/day, given in two divided doses for the first 2 days of therapy. This drug rapidly diminishes bacterial counts in experimental disease and has been effective in combination with other drugs in patients in whom erythromycin therapy has failed. Use of this drug for treatment of LD is not approved by the FDA. A recent small nonrandomized study has shown that adult patients treated with combination rifampin and clarithromycin had significantly longer hospital lengths of stay than did those treated with clarithromycin alone, with a trend to worse outcome in other outcome measures in those given combined therapy. Because the largest effect of rifampin in experimental animals is in the first 1 or 2 days of therapy, giving this drug for more than 2 days may do more harm than good. The best policy would be to use an alternative to erythromycin or clarithromycin in severe illness, and thus to avoid the question of combination therapy.[80] There is no good clinical or laboratory evidence that combining rifampin with either azithromycin or a fluoroquinolone is beneficial.

Treatment of extrapulmonary foci of infection does not appear to differ from treatment of LD without

extrapulmonary disease. The duration of therapy and indications for surgical drainage need to be assessed individually in these cases.

Response to Treatment

Most patients improve dramatically within a few days after initiation of specific therapy.[40,50,57,168] Response may be as rapid as 6 hours after administration of the first dose of therapy. Patients regain their appetite, lose symptoms of myalgia and fatigue, and feel better overall within a few days. Up to a week may be required for a patient to become completely afebrile, with longer periods sometimes required for severely immunosuppressed patients. The chest radiograph changes slowly and even may appear to worsen despite overall clinical improvement; progressive consolidation after 3 to 4 days of intravenous antimicrobial therapy is unusual. Because very severe immunocompromise can impair the ability of the cellular immune system to completely clear infection, some of these patients are prone to relapses of disease once antimicrobial therapy has been stopped, even after a long course of therapy.[85,159] The relapses can be insidious and manifest only as renewed immunosuppression. Profoundly immunosuppressed patients with LD who do not have recovery of immune function may benefit from prolonged suppressive antimicrobial therapy until they recover sufficient cellular immune function.

Failure to respond to appropriate therapy can be due to severe underlying disease, advanced pneumonia at presentation, coinfection with another microorganism, mistaken diagnosis, and complications of pneumonia. These complications can include pulmonary embolism, empyema, pancreatitis, myopericarditis, hepatitis, and soft tissue infections.

The mortality rate in otherwise healthy adults who are treated promptly is approximately 5 percent, whereas in treated immunosuppressed patients it is approximately 20 percent. Untreated fatality rates range from 15 to 20 percent in normally healthy patients and upward of 80 percent in immunosuppressed patients. However, very mild community-acquired LD in healthy adults that does not require hospitalization appears to have negligible mortality and may not require specific antibiotic therapy, although such a course may not be advisable.[176] Even in previously healthy patients, delayed therapy and development of respiratory failure are exceptionally poor prognostic factors.[62,142,170]

DIFFERENTIAL DIAGNOSIS

Other causes of atypical, or culture-negative, pneumonia may closely resemble LD. Mycoplasmal pneumonia usually is a milder illness not requiring hospitalization. Cough is a prominent symptom in mycoplasmal pneumonia, whereas it is not in LD. Neither rash nor otitis is found in LD. Laboratory abnormalities also are found more commonly in LD. Serologic testing may provide positive results for both diseases, a confusing finding that can be clarified by performing specific laboratory testing. Fortunately the treatment is the same for both diseases.

Psittacosis and Q fever may closely resemble LD. A history of bird or cattle exposure may be helpful, but its absence does not exclude either of these zoonoses. An interstitial rather than an acinar-filling infiltrate on chest radiograph would be point against LD. Pathogen-specific laboratory tests help in this differential diagnosis. A tetracycline can be used successfully for all three of these diseases.

Early in their evolution, some diseases may resemble LD. They include typhoid fever, acute coccidioidomycosis, influenza, the typhus or spotted fevers, and leptospirosis. Distinguishing these diseases on the basis of their clinical evolution, the laboratory results, and the exposure or travel history generally is easy.

Tularemia may pose a problem in differential diagnosis because immunologic test results for LD can be falsely positive in tularemia and because some of the growth characteristics of *Francisella tularensis* closely resemble those of *Legionella*. In regions endemic for tularemia, clinicians must work closely with the laboratory to facilitate this differential diagnosis. One case record of tularemia misdiagnosed as LD reported that the patient responded to erythromycin therapy.

Dual infection sometimes occurs in LD. Coexistence of LD with pneumonia caused by *Mycobacterium tuberculosis*, pneumococcus, *H. influenzae*, *Neisseria meningitidis*, *Pneumocystis jiroveci*, *Moraxella catarrhalis*, and various viral agents has been reported. Thus, dual infection should be suspected in patients not responding to therapy for pneumonia. Pathogen-specific laboratory tests often are useful in these cases.

CLINICAL SYNDROMES CAUSED BY OTHER *LEGIONELLA* SPECIES

Relatively few cases have been reported of disease caused by the non–*L. pneumophila Legionella* spp., with the major exception of *L. longbeachae*.[3,64,181] These reported cases have few differences in clinical findings, diagnostic methods, or treatment. Almost all cases of LD due to *Legionella* spp. other than *L. pneumophila* or *L. longbeachae*, have been reported to occur in immunocompromised patients; and because of these patients' underlying diseases and immunocompromise, the pneumonia severity and rapidity of response to therapy may be compromised. The lower frequency of these infections in normal hosts is most likely due to decreased virulence of the bacteria. *L. longbeachae* has a different mechanism of transmission than does *L. pneumophila* because *L. longbeachae* infections do not appear to be transmitted from water sources but rather from nonsterile potting soil.[25,108,163] Exposure to potting soil that has been exposed to high ambient temperatures, not washing hands after using the soil, and cigarette smoking are the major risk factors for this disease. The mode of spread and nosocomial reservoirs of the *Legionella* spp. other than *L. pneumophila* and *L. longbeachae* are not well defined. These infections are unlikely to be diagnosed by immunologic means, except for *L. longbeachae* infection in endemic regions (Australia and New Zealand), because few laboratories routinely test for all possible species. As with *L. pneumophila*, and even

more so for the non–*L. pneumophila Legionella* spp., treatment sometimes must be based solely on clinical suspicion without the benefit of confirmatory laboratory tests.

PONTIAC FEVER

Clinical Manifestations

Fever, myalgia, malaise, chills, and headache are the most common symptoms of Pontiac fever.[77] The symptoms may begin suddenly or have a more gradual onset for several hours. Many symptoms are respiratory, such as dry nonproductive cough, chest pain, and pharyngitis. Nausea is a common manifestation, but diarrhea and vomiting are less frequent. Neurologic symptoms including dizziness, confusion, and poor coordination also have been reported. Pontiac fever symptoms usually are at their worst within a day after onset of illness and gradually resolve over a 2- to 7-day period. Physical examination shows only tachycardia and fever. Leukocytosis has been the only laboratory abnormality reported. Chest radiographs show no abnormalities. Pulmonary function testing has not been performed in patients with Pontiac fever. Rechallenge by return to the contaminated building in the original Pontiac outbreak produced only a mild illness compared with first exposure; the length of time between first and second exposure was not stated clearly.

Diagnosis

The diagnosis of Pontiac fever primarily is one of exclusion.[40,168] Significant rises in anti-*Legionella* antibody level, combined with characteristic symptoms, and isolation of *Legionella* from an aerosol source are the diagnostic criteria. Rarely, *L. pneumophila* urinary antigen may be detected.[55] Detailed epidemiologic and environmental studies must be performed to diagnose Pontiac fever specifically. This is because of the nonspecificity of the symptoms and the ubiquitous presence of environmental *Legionella*. Definitive diagnosis of sporadic cases is difficult.

Treatment

Antimicrobial therapy does not appear to be effective for the treatment of Pontiac fever. Removal of the patient from the area of the contaminated water source appears to be the best means of management.

CHAPTER 138

Streptobacillus moniliformis (Rat-Bite Fever)

Kara Dubray • Carol A. Glaser

Rat bite fever is an acute febrile illness usually acquired by humans from the bite of a rat. The common term *rat bite fever* may be misleading because the disease actually encompasses two different etiologies and disease syndromes. Both *Streptobacillus moniliformis* and *Spirillum minus* are causative agents of rat bite fever; however, these organisms have different epidemiology, incubation periods, and clinical presentation. Streptobacillary rat bite fever, caused by *S. moniliformis*, is the focus of this chapter; *S minus* is discussed in Chapter 142.

Rat-bite fever caused by *Streptobacillus* is typically characterized by fever, rash, and arthritis. Although it is often acquired from the bite of a rat, other animals may be infected and modes of transmission other than a bite have been documented. Haverhill fever, for example, is acquired after ingestion of contaminated food or water. *S. moniliformis* is a zoonosis with worldwide distribution[41,119] and is the leading cause of rat bite fever in the United States.

HISTORY

The first description of rat bite fever is found in the 2500-year-old Indian *Compendium of Medicine*, the *Susruta Samhita*.[21] In this text, a description of the illness is given that remains valid today: "The blood of any part of the human body coming in contact with the semen of rats or scratched with their nails or teeth is vitiated and gives rise to the appearance of nodes, swellings, eruptions of circular erythematous patches on skin, pustules, violent and acute erysipelas, breaking pain in the joints, extreme pain in the body, fever, anemia, aversion to food, shivering, and horripilation." The disease also was known in ancient Japan, where treatment consisted of the local application of herbs and dynamite to cause an "explosion in the wound."[21]

The first modern accounts of the disease are found in a lecture by Professor Eli Ives at Yale University in 1831.[38] In 1900, Miyake[66] gave a detailed description of the disease, which he named *sodoku*, from the Japanese *so* ("rat") and *doku* ("poison"). The first case report was published in 1839.[116] Schottmüller,[96] Blake,[12] and Levaditi and colleagues[58] were the first to isolate and describe the causative agent of streptobacillary rat bite fever in 1914, 1916, and 1925, respectively. The organism has been known as *Streptothrix muris ratti* and *Streptobacillus muris minus* but currently is referred to as *S. moniliformis*.[50]

Haverhill fever was reported first in 1926 after an outbreak of epidemic illness in Haverhill, Massachusetts. In that outbreak, 86 cases developed and were traced to contaminated, unpasteurized milk.[75] The illness was referred to as *erythema arthriticum epidemicum*. Although this was the first published outbreak, in 1925 approximately 400 cases of a similar illness were reported in Chester, Pennsylvania.[33] The causative organism was isolated, described in detail by Parker and Hudson[70] in 1926, and given the name *Haverhillia multiformis*. It was later shown to be identical to *S. moniliformis*. The first outbreak in Britain was described in 1983 at a boarding school in Essex and affected more than 200 students; it was also believed to be related to contaminated raw milk.[72,100]

EPIDEMIOLOGY

Rats are estimated to compose one third of the mammalian population of the world, with numbers of approximately 10 billion.[41] More than 2 million animal bites are reported annually in the United States, and rat bites account for a small number (<1%), although the incidence is probably underreported.[31,41,44] A review of animal bites in Maryland during a 3-year period found that approximately 4.7 percent were caused by rats or lagomorphs.[25] According to another report, 40,000 rat bites are reported annually.[22] Among bitten patients, the risk for rat bite fever developing is significant, with reported rates between 4 and 11 percent.[83,115]

Between 10 and 100 percent of laboratory rats and 50 to 100 percent of wild rats carry *S. moniliformis* as normal nasopharyngeal flora and excrete it in their urine.[4,41,105] The disease also has been transmitted to humans from mice,[81] squirrels,[64] weasels,[27] gerbils,[117] and rat eating carnivores, such as cats,[43,65] dogs,[71,84] and pigs.[114] In addition, *S. moniliformis* can cause disease in turkeys,[67] guinea pigs,[56] koalas,[91] spinifex hopping mice,[52] and nonhuman primates (rhesus monkey).[109] In one study looking at colonization in dogs with confirmed rat contact, 3/10 animals had evidence of *S. moniliformis* by polymerase chain reaction (PCR) using mouth swabs.[118] Because many of these animals prey on rodents, they could pose a potential source of infection for humans.

Given the changing perception of rats and breeding as family pets, rat bite fever in the United States is shifting from a disease of poverty to a disease of pet owners, pet store workers, and laboratory workers. Children are

generally reported to account for at least 50 percent of rat bite fever cases and, indeed, half of all *S. moniliformis* isolates identified at the California state Microbial Diseases Laboratory between 1970 and 1998 involved children younger than 9 years of age.[47] Not surprisingly, children living in crowded urban centers or rural impoverished areas continue to be at greatest risk.[25,51,80,112] Recently, however, reports of rat bite fever are emerging among individuals who keep rats as pets.[4,8,24,110] Most of the other reported cases involve laboratory personnel who handle rats.[7]

Rat-bite fever usually is transmitted through the bite of a rat, but it also may be transmitted by rat scratches, contact with a break in the skin, mucosal contact (kissing a pet rat), or handling a dead animal.[17,24,36,92] Unlike typical rat bite fever, Haverhill fever is transmitted by the ingestion of food or water contaminated by rats, with previous outbreaks involving unpasteurized milk, ice cream (made from raw milk), and water.[62,75] Rat-bite fever was reported after varicella in a child who handled pet rats frequently while she had open skin lesions,[77] and septic arthritis caused by *S. moniliformis* was reported in a child who kissed pet rats.[49] One review of 12 pediatric cases documented 5 patients with exposure to pet rats.[69] In another study of 16 cases of *S. moniliformis* septic arthritis, the majority of patients with rat exposure involved rats as household pets.[26] A review of 65 detailed cases in the English literature from 1938 until 2005 showed 26 (40%) with wild rat exposure, 8 (12%) with laboratory rat exposure, and 3 (5%) with pet shop rat exposure. Twenty-two (34%) of the patients described an exposure not relating to a bite or a rat.[33]

Rat-bite fever has been reported worldwide; however, it is not a reportable disease, and the actual incidence is unknown. A report from the California state Microbial Disease Laboratory from 2001 reported an incidence of approximately 1.5 cases/year from 1970 to 1998, with more than half of the reported cases occurring after 1990. The report cited a possible increase in incidence after 1990; however, this is largely speculative because the numbers represent only confirmed cases.[47] Difficulty in isolating the organism, improved detection techniques, and an increase in physician awareness of the disease all may influence the reported rates. The mortality rate of rat bite fever has been reported to be 7 to 13 percent if left untreated[26,33,41]; however, the number of patients with mild or subclinical disease is not known.

BACTERIOLOGY

S. moniliformis is a pleomorphic, microaerophilic, nonmotile, nonencapsulated, non–acid-fast, gram-negative bacillus. It measures 1 to 5 μm in length.[50] The organism is oxidase- and catalase-negative and will ferment glucose, maltose, fructose, galactose, and salicin.[50] *S. moniliformis* is facultatively anerobic[35,41] and is the only species in its genus.

The organism is fastidious and requires special handling for isolation. Optimal growth is achieved in trypticase soy agar or broth supplemented with 20 percent horse or rabbit serum.[70] Alternatively, brain-heart infusion broth supplemented with "Panmede" (a papain digest of ox liver) also has been shown to support the growth of *S. moniliformis*.[101] Sodium polyanethol sulfonate (SPS), which is added to most aerobic blood culture bottles at a concentration of 0.05 percent, will inhibit the growth of *S. moniliformis* at concentrations as low as 0.0125 percent.[101] Blood culture bottles without SPS added should be used for primary isolation of *S. moniliformis* when rat bite fever is suspected. Another option is to inoculate twice the amount of blood than recommended by the manufacturer into the blood culture bottle.[42] Material from lymph nodes and abscesses also may be useful material for isolation of the organism.[42] One other alternative is to inoculate citrated blood directly into broth. Cultures should be incubated at 35° to 37°C (95° to 98.6°F) in a humid environment with a partial pressure of carbon dioxide between 8 and 10 percent.

The morphologic characteristics of the bacterium depend on the environment.[69] In favorable media, the typical appearance is that of short rods that may grow in chains. In other conditions, the organism tends to grow in long, interwoven filaments that commonly contain beaded and fusiform swellings throughout their length. The Latin term *moniliformis* translates to "in the form of a necklace." In broth culture, colonies usually appear in 2 to 10 days.[50] The colonies are white, soft "puffballs" measuring 1 to 2 mm in diameter (Fig. 138-1).[4] On blood agar plates, the colonies are round, gray, and glistening and measure 1 to 2 mm in diameter after 2 to 3 days of incubation.[50]

Stable L-forms of the organism develop spontaneously in vivo or in vitro. These cell wall–deficient forms have a "fried egg" appearance with dark centers and lacy edges when grown on solid media.[50,73] The L form is considered

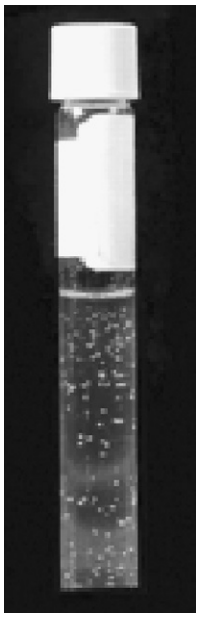

FIGURE 138-1 ■ The colonies are white, soft "puffballs" 1 to 2 mm in diameter. (From Albedwawi S, LeBlanc C, Shaw A, et al. A teenager with fever, rash and arthritis. *CMAJ* 2006;**175**:354.)

nonpathogenic, even though spontaneous conversion between the two forms has been reported in vitro and may be responsible for relapses and resistance to therapy, although this is not certain.[33,40,98] L forms are resistant to penicillin and other antibiotics active against the bacterial cell wall. These variants may be deposited in tissues and prolong the symptoms of illness.[29]

CLINICAL MANIFESTATIONS

Streptobacillary rat bite fever often has an incubation period of less than a week, with the usual range from 3 to 10 days. Incubation has been documented up to 3 weeks.[3] Young children may have shorter incubation times. Typically the bite site, if known, is well healed (as opposed to spirillary rat bite fever) and often is not evident on examination. Most individuals have evidence of contact with a rat, although not necessarily a bite history. Up to 30 percent of individuals are reported to have no history of a bite or scratch.[18]

A review of 65 patients showed an age range of 2 months to 87 years. Symptoms described included fever (92%), polyarthralgias (66%), rash (61%), nausea and vomiting (40%), headache (34%), myalgias (29 %), and sore throat (17%). White blood cell counts were often normal, with polymorphonuclear cell and band form predominance. Only 5 patients (8%) demonstrated white blood cell counts higher than 15,000/mm^3.[33]

Rash develops usually within a few days of fever onset (range, 1 to 8 days) in approximately 75 percent of patients. The rash may be generalized, but more often is prominent on the extremities and frequently involves the palms and soles (Figs. 138-2 and 138-3).[1,24,61,73] Rash has been described as maculopapular, petechial, purpuric, pustular, hemorrhagic, vesicular, and bullous.[3,33,41,53] Desquamation is reported in approximately 20 percent and the rash may take several weeks to resolve.[41]

Arthralgia or arthritis with or without joint effusion also develops in more than 50 percent of patients classically within the first week of illness. Arthritis usually involves large joints, but also may affect small joints, and tends to be migratory, nonsymmetric, and extremely painful.[6,36,51,97] Arthritis may be monoarticular or polyarticular and acute or subacute. Although multiple joints are usually affected, at least two cases of monoarticular involvement in children have been described involving the hip joint.[30,48] With untreated infection, persistent or recurrent episodes of fever and arthritis may be experienced.[37,107]

Isolation of *Streptobacillus* from joint fluid is not common and the arthritis from rat bite fever is considered to be nonsuppurative with sterile joint fluid cultures. It has been hypothesized that *Streptobacillus* may cause a direct infective arthritis and an immune-mediated phenomena, although this is not well understood.[26] At least two recent reviews of septic arthritis caused by *S. moniliformis* (defined by isolation from joint or synovial fluid) with at least 17 individual cases have been reported.[26,113] Rash was present in a minority of patients only. Arthritis may present as a septic hip in children and may mimic rheumatoid arthritis in older patients with peripheral joints affected.[57] Patients with underlying osteoarthritis may be predisposed to this complication. The prognosis is quite favorable overall, with all patients in these series recovering with treatment.[26,113]

Complications of *S. moniliformis* infection include anemia,[86] cutaneous or subcutaneous abscess formation,[16,48,73,111] interstitial pneumonia,[63,98] mastoiditis,[74] meningitis,[8,98] pericardial effusion,[15] pancreatitis, prostatitis,[119] septic arthritis,* and overwhelming sepsis.[98] Abscess formation in several different organs, including the brain,[28] the female genital tract,[73] and the spleen,[20] has been reported. Unusual and potentially devastating complications include chorioamnionitis[34] and periarteritis nodosa,[79] and endocarditis.

The most frequent serious complication is bacterial endocarditis, with nearly 50 percent mortality.† At least

FIGURE 138-2 ■ Within 1 to 8 days after the onset of fever, a pink-red maculopapular rash develops in approximately 75 percent of patients and frequently involves the palms and soles. (From Albedwawi S, LeBlanc C, Shaw A, et al. A teenager with fever, rash and arthritis. *CMAJ* 2006;**175**:354.)

†References 9, 19, 61, 82, 85, 90, 103.

20 cases of endocarditis have been reported in the literature with over half of the cases reported prior to 1968.[19,33,90,102] Many patients reported had underlying valvular disease.[33] In a review of 17 cases, the majority of patients (12) had systemic symptoms, including fever, rash, arthritis.[90] Of 14 cases in which clinical symptoms were reported, murmur was noted in 100 percent, petechiae in 13 percent, Osler's nodes in 13 percent, hepatosplenomegaly in 33 percent, anemia in 33 percent, and cardiac dysrhythmia in 13 percent.[90] At least 6 cases have involved children younger than 18 years, with the youngest just 2 months of age.* Of the 6 children, 5 died during the acute illness.

At least seven fatal pediatric cases have been reported, the majority with endocarditis. Most deaths were described in the 1930s and 1940s among older children with endocarditis. In the 1980s, two separate cases of infant deaths related to rat bite fever were described. One case was a 3-month-old infant with endocarditis, and the other was a 2-month-old infant with disseminated disease. In 2011, another fatal case in a 14-month-old infant with disseminated disease was described with autopsy findings similar to those of the 2-month-old infant, including interstitial pneumonitis, meningitis (with isolation of the organism from cerebrospinal fluid [CSF]), and hepatomegaly.[10,50,69,86]

Haverhill fever is similar to streptobacillary rat bite fever, with an abrupt onset of fever and chills (100%), rash (95%), and arthritis (97%).[2,62] Generally, the incubation period is 1 to 3 days. Upper respiratory and gastrointestinal problems are common. Multiple recurrences of fever are found rarely, and the rash tends to be small and uniform in size.[63]

PATHOPHYSIOLOGY AND PATHOLOGY

Factors influencing the virulence of *S. moniliformis* are not well described. The organism has an affinity for synovial tissue in both animals and humans, but the mechanisms by which *S. moniliformis* produces arthritis are unknown.† Studies performed in mice indicate that *S. moniliformis* is only slightly immunogenic and produces mild leukocytosis and minimal homologous antibody production.[94,95] In addition, the organism is resistant to phagocytic destruction.[94] These factors may allow chronic infection to develop. Again the organism may spontaneously convert to the cell wall–deficient form (or L form), and this has been speculated to be responsible for relapsing disease.

The pathologic features of streptobacillary rat bite fever have been described in a limited number of autopsy reports. Common features include ulcerative endocarditis with secondary septic embolization in the liver and spleen, septic arthritis, and interstitial pneumonia.[12,98] Mononuclear meningitis and erythrophagocytosis also have been reported.[98] In a pediatric autopsy report, in which *Streptobacillus* grew from the CSF, mild flattening of the cerebral gyri with mild collapse of the ventricular system was seen, but no major histopathologic changes were noted in the brain. The kidneys had findings consistent with disseminated intravascular coagulopathy. The small and large intestine, liver, thymus, thyroid gland, larynx, and heart showed mild to moderate autolysis, but no other major histopathologic changes.[10] In most reports, the site of the bite reveals little histologic evidence of inflammation.[63]

DIAGNOSIS

Two recent fatal cases reported in the Centers for Disease Control and Prevention (CDC) *Morbidity and Mortality Weekly Report* highlight the importance of considering rat bite fever in the differential.[18] The diagnosis of rat bite fever requires a high index of suspicion on the part of the physician. The diagnosis is suggested in a febrile patient with a history of exposure to rats, but in most clinical settings, the exposure history is not elucidated until after the diagnosis is made. It should be considered in patients who present with fever, rash, and arthritis.[104]

Nonspecific laboratory findings may include an elevation in the white blood cell count,[12] usually in the range of 10,000 to 30,000 cells/mm^3 with a left shift, mild anemia, and a false-positive serologic test for syphilis, which may occur in 25 percent of patients.[86] Direct visualization of the organism on Giemsa stain of blood or joint fluid may suggest the diagnosis. Serologic assays are not currently available for humans. An enzyme-linked immunosorbent assay has been developed to monitor infection in rodent colonies.[14]

Molecular techniques may be an effective means for detection of *S. moniliformis* from humans and animals and may offer an alternative to traditional culture methods.[5,11,13,38] Broad-range PCR amplification of a part of the 16S rRNA gene followed by sequencing allowed the detection and identification of *S. moniliformis* in blister fluid of a patient reported in 1991.[11] A PCR assay specific for *S. moniliformis* was described by Boot and colleagues[14] using primers designed on the basis of 16S rRNA gene base sequence data of human and rodent strains of *S. moniliformis*, and similar assays have been used subsequently.[68,118] At least one report described a positive PCR obtained from a bite site.[68] PCR testing is becoming more refined, with a 2008 publication describing new primers to amplify the 16S rRNA gene of *Streptobacillus* spp. more specifically than prior tests.[55] Currently PCR testing is not widely available and is not yet validated for diagnostic use, but may be requested from the CDC and reference laboratories.

S. moniliformis has been cultured from blood, joint fluid, abscesses, pericardial fluid, meninges, and tissues obtained at autopsy.[10,17] The organism has strict growth requirements, and the choice of culture media and technique is of critical importance for optimal growth of the bacterium (see the discussion of bacteriology). Whenever this agent is suspected, it is helpful to alert the laboratory that will be performing isolation. In general, routine aerobic blood cultures are not satisfactory for isolation. If the organism is isolated, it may be identified rapidly by gas-liquid chromatography. *S. moniliformis* has a

*References 63, 78, 87, 90, 98, 103, 106.
†References 45, 46, 51, 54, 59, 95, 108.

characteristic fatty acid profile, with major peaks being palmitic, linoleic, oleic, and stearic acid.[73,88] Electrophoretic protein patterns also have been described that can distinguish Haverhill fever strains from rat bite fever strains.[23]

The differential diagnosis for streptobacillary rat bite fever includes illness caused by *S. minus* (see Chapter 142). It also includes all relapsing fevers, such as *Borrelia recurrentis*, malaria, and typhoid. Rocky Mountain spotted fever must be considered,[60] as well as other infectious entities, including leptospirosis, Lyme disease, disseminated gonococcal infection, meningococcemia, brucellosis, and syphilis. Viral infections also may be mistaken for rat bite fever. Acute rheumatic fever should be considered as well. The frequent symmetric involvement of small joints of the hands can be particularly suggestive of rheumatoid arthritis.[51] Other noninfectious entities include drug reactions, collagen vascular disease, and other rheumatologic conditions.

TREATMENT AND PREVENTION

Although fatal in some cases, streptobacillary rat bite fever is a very treatable disease usually responsive to antibiotics. The treatment of choice for *S. moniliformis* is penicillin G. Either procaine penicillin intramuscularly or aqueous penicillin intravenously is acceptable.[3,79] Tests of *S. moniliformis* antibiotic susceptibility by the disk diffusion method usually demonstrate sensitivity to penicillins, cephalosporins, carbapenems, aztreonam, clindamycin, erythromycin, nitrofurantoin, bacitracin, tetracycline, teicoplanin, and vancomycin; intermediate susceptibility to aminoglycosides, fluoroquinolones, amikacin, and chloramphenicol; and resistance to trimethoprim-sulfamethoxazole, polymyxin B, and nalidixic acid.[119] Only one penicillin-resistant *S. moniliformis* strain has been demonstrated, and that was more than 50 years ago.[33] A 1965 study noted the rapid response to penicillin was in stark contrast to other regimens.[79]

In adults, the dosage of penicillin should be no less than 400,000 to 600,000 IU/day of IV aqueous penicillin G continued for at least 7 days and up to 10 to 14 days.[33,39,53,69,85] Treatment with penicillin for up to 28 days or more has been reported in cases of presumed septic arthritis.[113] If no response is seen within 2 days, the dosage should be increased to 1.2 million IU/day.[79] Children have been treated successfully with 20,000 to 50,000 IU/kg/day of intravenous penicillin, up to a maximum of 1.2 million IU/day.[99] No controlled studies have been done on duration of intravenous versus oral therapy. In children, some suggest after 5 to 7 days of intravenous therapy with good response, treatment may be completed with oral penicillin.[18,33,53] For mild cases, oral penicillin V 1 to 2 g/day in divided doses may be given.[39,99]

In penicillin-allergic adults, both streptomycin and oral tetracycline have been effective.[18,76,90,97] The suggested dose is oral tetracycline 500 mg 4 times per day or intramuscular streptomycin 7.5 mg/kg twice daily.[75] In children, streptomycin and oral erythromycin have been used, but treatment failures with oral erythromycin have been reported.[48] Clarithromycin has been used successfully to treat an adult with rat bite fever.[110] Antibiotics, including cefuroxime, cefotaxime, gentamicin, and ciprofloxacin, have good activity against *S. moniliformis* in vitro.[32] Several reports document successful treatment with cephalosporins, including cefuroxime and ceftriaxone.[17,24,49,85] At least one case of suspected rat bite fever is reported to have been treated successfully with amoxicillin.[17]

Optimal therapy for *S. moniliformis* endocarditis is based on case reports given the rarity of disease. High-dose aqueous intravenous penicillin G or procaine penicillin intramuscularly is the treatment of choice. Some experts suggest using penicillin in combination with streptomycin or gentamicin, although limited data exist.[33] For adults, daily administration of intramuscular procaine penicillin G at 4.8 million IU has been recommended if the isolate is susceptible (0.1 μg/mL).[33,90] If the isolate is more resistant, intravenous penicillin G 20 million IU/day should be used.[90] In children, the dosage is intravenous aqueous penicillin 160,000 to 240,000 IU/kg/day (96 to 144 mg/kg/day), up to the adult maximum of 20 million IU/day.[33,90,99] Treatment should be continued for at least 4 weeks, although up to 6 weeks may be considered based on treatment of other types of bacterial endocarditis.[33] In a review of 16 patients with endocarditis, 4 patients who did not receive specific antimicrobial therapy died, as did 3 patients who received less than 1 million units of penicillin per day. Only 2 patients who received more than 1 million units of penicillin per day died, and one of those patients died suddenly 4 months after valve replacement.[90]

Antibiotic susceptibility testing of the organism should be performed and minimum inhibitory and bactericidal concentrations for several antimicrobial agents determined. It is desirable to have a peak serum minimum bactericidal concentration of at least 1:8. Recently, successful treatment of endocarditis with ceftriaxone in combination with gentamicin was reported.[85] Penicillin G is also the drug of choice for Haverhill fever. Most individuals can be treated as outpatients.

PREVENTION

Rat-bite fever can be prevented by controlling rodents in urban areas, properly handling rodents, and avoiding unpasteurized milk products. Individuals who own rats and those who work with rodents should receive anticipatory guidance regarding the handling of these animals and the signs and symptoms of rat bite fever. If a rat bites an individual, prophylactic antibiotics, such as amoxicillin or amoxicillin-clavulanic acid, may prevent rat bite fever, but current data do not support the routine use of antibiotics after all rat bites. Some researchers suggest that because of the serious nature of rat bite fever in young infants, infants younger than 3 months who are bitten by a rat should receive antibiotic prophylaxis.[60]

CHAPTER 139

Bartonella Infections

Leigh M. Howard • Kathryn M. Edwards • Barbara Stechenberg

DEFINITION

Bartonella species cause infection in both zoonotic and human hosts and give rise to a wide spectrum of acute or chronic disease symptoms. The development of different manifestations of *Bartonella* disease depends on the immune status of the host. Until 1993, only three human diseases were known to be caused by *Bartonella* species.[3] However, advances in molecular techniques have led to the reclassification of several pathogens, with the family Bartonellaceae, genus *Bartonella*, expanding to include more than 30 validated species.[11] Several of these species have been associated with human disease (Table 139-1). The current *Bartonella* genus was created by merging with the genus *Rochalimaea* based on both DNA-DNA hybridization data and comparison of 16s rRNA gene sequences.[12] Of the members of the genus *Rochalimaea* that have been reclassified as *Bartonella* spp., *Bartonella henselae*, the cause of cat-scratch disease, is the most common *Bartonella*-associated infection in children. *Bartonella* infections other than cat-scratch disease seldom occur in children and are only discussed briefly later in the chapter.

MICROBIOLOGY

Comparisons of the 16s rRNA-encoding genes have shown that the *Bartonella* genus is most closely related to *Brucella* and *Agrobacterium*. *Bartonella* are small, gram-negative, fastidious coccobacilli or slightly curved rods that grow best on enriched blood–containing media in 5 percent carbon dioxide. Colony morphology varies from small, dry, gray-white colonies to smooth, creamy yellow colonies. Although the optimal growth temperature for *B. bacilliformis* is 28°C, optimal temperatures for other *Bartonella* species range from 35 to 37°C. Even with optimal conditions, these organisms require 1 to 6 weeks to grow in culture.[13] Increasingly, the presence of *Bartonella* organisms is detected by molecular methods.

TABLE 139-1 ***Bartonella* Species Causing Human Disease**

Bartonella Species	Country of First Cultivation	Year of Description	Reservoir Host/Vector	Human Disease
B. alsatica	France	1999	Rabbit	Endocarditis, lymphadenopathy
B. bacilliformis		1909	Human/sand fly	Carrión disease, Oroya fever, verruga peruana
B. clarridgeiae		1996	Cat/cat flea	Cat-scratch disease
B. elizabethae	United States	1993	Rat	Endocarditis, neuroretinitis
B. grahamii	United Kingdom	1995	Rat, insectivore	Neuroretinitis
B. henselae		1990	Cat/cat flea	Cat-scratch disease, endocarditis, bacillary angiomatosis, bacillary peliosis hepatis, Parinaud oculoglandular syndrome, neuroretinitis, osteomyelitis, arthropathy, bacteremia with fever
B. koehlerae	United States	1999	Cat	Endocarditis
B. mayotimonensis	United States	2009	Unknown	Endocarditis
B. melophagi	United States	2006	Unknown	Bacteremia
B. quintana		1920	Human/body louse	Trench fever, endocarditis, bacillary angiomatosis
B. rochalimae	United States	2007		Bacteremia, fever, splenomegaly
B. tamiae	Thailand	2008		Febrile illness
B. vinsonii subsp. *arupensis*	United States	1999	Dog, rodent/ticks	Bacteremia with fever, endocarditis
B. vinsonii subsp. *berkhoffii*	United States	1999	Dog	Endocarditis
B. washoensis		2000	Ground squirrel	Myocarditis

Adapted from Rolain JM, Rauoult D. *Bartonella* infections. In: Goldman L, Schafer AI, et al, editors. *Cecil medicine.* 24th ed. Philadelphia: Saunders; 2012, p 1907.

Organisms of the *Bartonella* genus may colonize human endothelial cells or may persist as intraerythrocytic parasites in the host.

CAT-SCRATCH DISEASE

Cat-scratch disease (CSD), caused by *Bartonella henselae*, is an acute, self-limited infection that begins as a papule or nodule at the site of a scratch or bite by a cat, followed by regional lymphadenopathy. In a small number of patients, more serious systemic complications result, including involvement of the central nervous system, liver, spleen, bone, heart, eyes, or skin. Although CSD was recognized as a clinical entity in the 1930s, the first written report, by Debré from France, was not published until 1950.

Etiology

For more than 40 years, numerous unsuccessful attempts were made to isolate an organism from nodes of patients with CSD. The first clue emerged in 1983, when Wear and colleagues,[73] using Warthin-Starry silver stain, demonstrated small, pleomorphic, gram-negative bacilli in lymph nodes and skin papules from patients with CSD. Then, in 1988, an organism was isolated by English and associates[23] from the lymph nodes of patients with CSD and subsequently termed *Afipia felis*. However, the discovery of bacillary angiomatosis and its association with *B.* (formerly *Rochalimaea*) *henselae* suggested that it might be the agent responsible for CSD.[59] In 1992, Regnery and coworkers,[58] using indirect fluorescent antibody (IFA) assays, demonstrated elevated antibodies to *B. henselae* in serum samples from patients with suspected CSD. We and others using enzyme-linked immunosorbent assays (ELISAs) demonstrated that patients with CSD had significant serologic responses to *B. henselae* and *Bartonella quintana* but not to *A. felis*. These data further supported that the causative agent of CSD was related antigenically to the *Bartonella* genus and not to *Afipia*.[70] In a physician survey to identify cases of CSD occurring during a 13-month period in cat owners in Connecticut, Zangwill and colleagues[75] demonstrated that of 45 patients with clinical CSD, 38 had antibody titers of 1:64 or higher for *B. henselae* as compared with only 4 of 112 samples from controls (p <.001). Finally, the use of polymerase chain reaction (PCR) confirmed the causative agent of CSD as *B. henselae*.[2] Eventually, PCR amplification was used to detect *B. henselae* not only in purulent material aspirated from involved nodes but also in CSD skin test material.[1,32,66] Subsequently, *B. henselae* has been cultured from lymph nodes obtained from patients with CSD.[29]

Transmission

Domesticated house cats are healthy carriers of *B. henselae*, and cat fleas *(Ctenocephalides felis)* play a major role in cat-to-cat transmission. Approximately 90 percent of patients with CSD have a history of exposure to cats, particularly a scratch or bite from a kitten with fleas. Although cats remain asymptomatic, they serve as a persistent reservoir for *B. henselae*. Reported *B. henselae* seroprevalence rates in cats vary. The southeastern United States, Hawaii, and coastal California have the highest seroprevalence in cats (40% to 54.7%), whereas rates are much lower (3.7% to 6.7%) in the Rocky Mountain and Midwestern regions.[39] Blood samples obtained from

domestic and impounded cats in the San Francisco Bay region grew *B. henselae* 41 percent of the time. *B. henselae* also was detected in fleas from infected cats by both direct culture and PCR, although no data support flea-to-human transmission. Interestingly, Chang and colleagues[18] found that *Ixodes pacificus* and *Dermacentor* ticks from five of six California counties were also PCR positive for *B. henselae*. Coinfections with *B. henselae* and *Borrelia burgdorferi* have been described in three patients in New Jersey.[24] *Ixodes* ticks obtained from two of the three households of patients with CSD were PCR positive for *B. henselae*. Thus, these observations should alert clinicians to consider *Bartonella* infection in humans after tick bites, although its frequency of transmission is unknown.

Epidemiology

CSD most commonly affects children and young adults worldwide, with regional variations. The Centers for Disease Control and Prevention estimates that, overall, more than 22,000 cases of CSD occur each year in the United States. Using a national inpatient database, Reynolds and coworkers estimated that 437 pediatric hospitalizations for CSD (0.60 per 100,000 population) occurred in 2000, with 60 percent of them occurring between July and October. Rates were higher in children younger than 5 years and higher in the southern states, underscoring the regional differences. Zangwill and colleagues[75] suggested that the seasonality of CSD could be explained by the breeding patterns of cats and fleas. Cats often become pregnant in late spring or early fall, and after a 9-week gestation period, kittens are birthed in early fall or midwinter. Flea breeding peaks during the late summer months.

Pathobiology

Histopathologic examination of the primary inoculation lesion demonstrates dermal necrosis, with variable numbers of histiocytes and occasional multinucleated giant cells accompanied by scattered microabscesses with neutrophils, eosinophils, lymphocytes, and plasma cells. The epidermal changes are nonspecific and consist of parakeratosis, hyperkeratosis, edema, and exocytosis of inflammatory cells. Characteristic findings in the lymph nodes, similar to the primary lesion, include follicular hyperplasia, focal cortical necrosis, and necrotizing granulomas with central microabscesses and palisading histiocytes. A perivascular neutrophilic infiltrate may also be present. Subsequently, the lesions progress to "stellate microabscesses" within small cortical granulomas. Warthin-Starry or Steiner silver impregnation stains may reveal pleomorphic bacilli in clusters or short chains within the areas of central necrosis or around small vessels, particularly in early lesions. Granulomas with microabscess formation also can be found in the liver, spleen, and bone. Because other organisms such as tularemia, fungi, and mycobacteria may have similar histopathologic characteristics, the histopathologic findings must be correlated with the clinical findings and other laboratory studies, including serology, culture, or PCR.

In vitro studies have identified several additional properties of *B. henselae*. When *B. henselae* infects endothelial cells, it induces activation of nuclear factor kappa B and expression of adhesion molecules, an important step in the pathogenesis of CSD and bacillary angiomatosis.[18,30] Animal studies have shown that interferon-γ–mediated activation of macrophages is involved in clearing *B. henselae* infection and that microbicidal activity is mediated to a large extent by nitric oxide.[50] A role for cell-mediated immunity in CSD is suggested by the positive skin test reaction to injected material aspirated from cat-scratch nodes and the granulomatous lesions noted in biopsy specimens.

Clinical Manifestations and Course

The most common clinical manifestation, often referred to as *typical CSD*, is a gradually enlarging regional lymph node occurring 1 to 3 weeks after a scratch or bite from a cat. An inoculation site, which often appears as a red papule 3 to 5 mm in diameter, can be detected in two thirds of patients. Constitutional symptoms of malaise, fatigue, anorexia, emesis, and headache are common but usually are mild. Fever occurs in fewer than half the patients with typical CSD, thus rendering the common name "cat-scratch fever" inexact. Physical examination generally reveals a skin papule at the inoculation site and regional lymphadenopathy (Fig. 139-1). In approximately 50 percent of cases, lymphadenopathy is the only manifestation of the disease and occurs most commonly in the upper extremity (axillary or epitrochlear lymph nodes, 46.1%), the head and neck area (cervical or submandibular, 26.1%), and the lower extremities (femoral or inguinal, 17.5%).[15] Supraclavicular lymphadenopathy, which often raises concern for malignant neoplasm, occurs rarely (2% of typical CSD). Suppuration of the involved lymph nodes occurs in about 10 percent of patients (Fig. 139-2). More unusual manifestations of CSD include neuroretinitis, subacute iritis, optic neuritis, focal chorioretinitis, and the oculoglandular syndrome of Parinaud (Fig. 139-3). Patients with this syndrome have painful conjunctivitis without eye drainage and preauricular adenopathy. Recovery is spontaneous without sequelae within 2 to 4 months after onset.

Hepatosplenic CSD is an important cause of prolonged fever in children and should be included in the differential diagnosis of fever of unknown origin. Often these children will have fever for several weeks (mean, 3 weeks), abdominal pain (occurring in about two thirds of patients),[5,22] joint pain, headache, weight loss, and chills. Significant lymphadenopathy is lacking in more than 50 percent of cases, thus rendering the diagnosis problematic. Hepatic or splenic enlargement (or both) is found in half of these children, but hepatic transaminase levels usually are normal. Erythrocyte sedimentation rates invariably are elevated and frequently are greater than 100 mm/hr. Abdominal imaging usually demonstrates typical granulomatous lesions in the liver or spleen that often are diagnostic of this entity (Fig. 139-4). Although both ultrasonography and computed tomography (CT) will demonstrate these lesions, a number of reports suggest that the ultrasound evaluation is more sensitive

FIGURE 139-1 ■ Cat-scratch disease involving an axillary lymph node with a primary granuloma of the upper part of the arm. Note that the primary lesion is within the line of a healed scratch. (Courtesy Hugh A. Carithers, MD.)

FIGURE 139-2 ■ Purulent material aspirated from an epitrochlear lymph node of a child with cat-scratch disease. The primary lesion was on the index finger.

than CT.[43,46] As is the case with other infections causing hepatosplenic granulomas, late calcification has been described.

Neurologic complications have been reported in approximately 2 percent of CSD cases with an estimated 51 pediatric hospitalizations in 2000.[62] Encephalopathy, the most common manifestation, typically occurs 1 to 6 weeks after the onset of lymphadenopathy. Fever and seizures develop abruptly, followed by confusion, disorientation, and, occasionally, combativeness. Status epilepticus is well described. Cerebrospinal fluid examination frequently is normal, but occasional mild pleocytosis or elevated protein levels are seen. Electroencephalographic findings frequently are abnormal, with diffuse slowing or focal abnormalities. CT of the head generally is normal. Resolution of seizures and normalization of mental status often occur as suddenly as does the onset. Neurologic recovery commonly occurs within weeks and almost always is complete within a year. Persistent deficits or a need for prolonged anticonvulsant therapy have been reported in only a few cases.[34,60] Two immunocompetent children have been reported to have central nervous system infection associated with *B. quintana* with a similar symptom constellation.[52]

Osteomyelitis caused by *B. henselae* is well described in the literature, with one report documenting its occurrence in 2 of 1200 cases. With improved imaging, serologic methods, and PCR for diagnosis, it is now clear that *B. henselae* osteomyelitis can occur as part of a disseminated infection, in the setting of otherwise typical CSD, or as a seemingly isolated manifestation.[37,72] The pathogenesis is not clear, but it probably represents

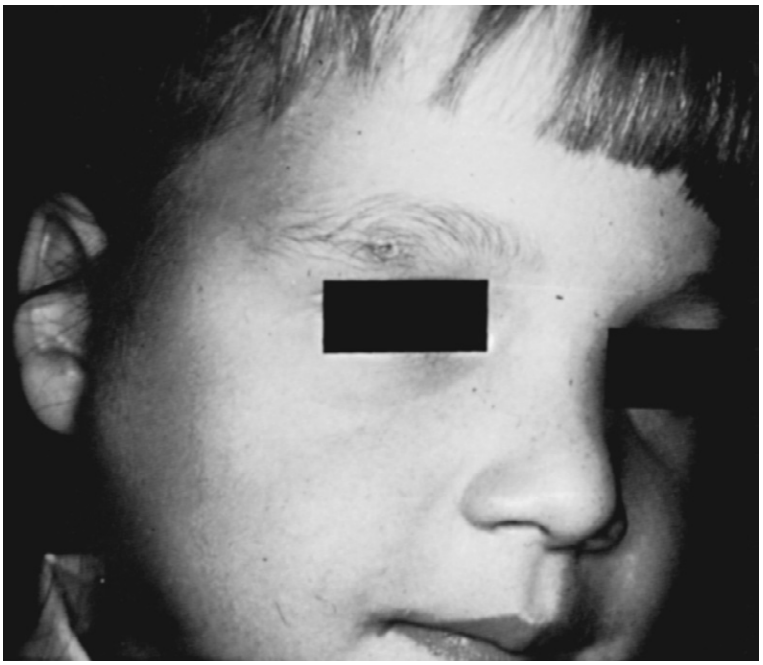

FIGURE 139-3 ■ Child with the oculoglandular syndrome of Parinaud as a manifestation of cat-scratch disease. Note the parotid swelling and the primary site in the right eyebrow. (Courtesy James D. Cherry, MD.)

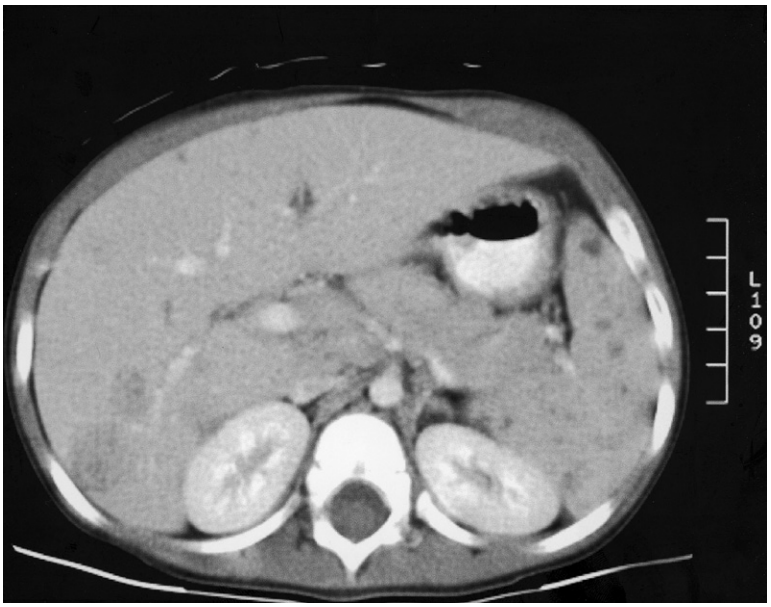

FIGURE 139-4 ■ Multiple hypodense lesions in the liver and spleen seen on CT in a child with prolonged fever, abdominal pain, and positive *Bartonella henselae* serology.

hematogenous spread, but local spread from a lymph node or abscess has been reported. Although the presentation of osteomyelitis may be acute, many patients have weeks to months of pain and intermittent fever before the diagnosis is made. A high proportion of reported cases involve the axial skeleton, most commonly the vertebral column. In a review of 47 cases by Hajjaji and colleagues,[35] lesions in the vertebrae or pelvic girdle were present in more than 50 percent of cases. Involvement of the long bones of the limbs, the sternum, and the skull has also been described. Although single-site involvement is typical, multifocal involvement was present in 28 percent of the cases in Hajjaji and colleagues' review.[35] Most commonly, the bony lesions identified by plain film, CT, or magnetic resonance imaging (MRI) are osteolytic. MRI also may show periosteal reactions, marginal sclerosis, and bone marrow lesions without cortical destruction, which are seen as hyperintense foci on T2-weighted images.

Patients with CSD also may have skin lesions other than at the inoculation site, including maculopapular rash, erythema nodosum, and petechiae due to thrombocytopenia. Molecular techniques have also documented hepatitis, hemolytic anemia, atypical pneumonia, pulmonary nodules, an infectious mononucleosis–like syndrome, and disseminated bartonellosis. Bacillary angiomatosis (mixed neovascular and inflammatory lesions in the skin or viscera), bacillary peliosis (dilated

capillaries or multiple blood-filled cavernous spaces in the liver, spleen, or lymph nodes), and relapsing fever with bacteremia due to *B. henselae* also can develop in immunocompromised subjects.[48]

ENDOCARDITIS

Epidemiology

Bartonella spp. have been reported as the cause of endocarditis in more than 100 cases,[56] with most cases in adults and several in adolescents. Often the cultures are negative.[7,54,55,68] In a series from a large referral laboratory in France *Bartonella* species accounted for 28 percent of culture-negative endocarditis, while in another report *Bartonella* accounted for only 3 percent of the culture-negative cases. *B. quintana* predominates and accounts for roughly 75 percent of the cases of endocarditis. *B. henselae* causes most of the remaining cases, and other species (*B. elizabethae* and *B. vinsonii*) have been reported in isolated cases. The epidemiologic characteristics of the patients differ considerably between the main two causative species. *B. quintana* endocarditis is highly associated with homelessness, chronic alcoholism, and body lice and is less likely to occur in the setting of cat exposure and underlying valvular heart disease. Endocarditis cases due to *B. quintana* also have been described in persons immunocompromised by infection with human immunodeficiency virus (HIV).[55,67] In contrast, *B. henselae* endocarditis occurs most often in patients with underlying valvulopathy (90%) and clearly is linked to exposure to cats or fleas.[27]

Clinical Manifestations

Bartonella endocarditis has a subacute presentation with fever, heart murmur, and often evidence of heart failure. Prolonged fever, night sweats, and profound weight loss also may occur. The aortic valve usually is affected; right ventricular or prosthetic valve involvement is an unusual finding. Valvular surgery is needed in many cases, often owing to delay in diagnosis.

BARTONELLOSIS (CARRIÓN DISEASE)

Bartonellosis is a term that has been used to describe a distinct disease seen in Peru, Ecuador, and Colombia caused by *Bartonella bacilliformis*. *B. bacilliformis* causes two distinct illnesses: Oroya fever, a severe febrile hemolytic anemia, and verruga peruana, an eruption of hemangioma-like lesions.

The first written account of bartonellosis is attributed to Gago de Vadillo, who published a treatise on the subject in 1630. Then, in 1764, Cosme Bueno first described the vector of this disease and of cutaneous leishmaniasis as the uta or sand fly.[36] In the mid 1800s an epidemic occurred that took the lives of hundreds.[65]

In 1885, a Peruvian medical student (Carrión) was collecting data on the geographic distribution and clinical features of verruga peruana. To study disease symptoms in the pre-eruption period of verruga, he inoculated himself with material taken from a patient with verruga. Within 21 days after inoculation he became symptomatic, developed classic Oroya fever, and died. In 1905, Alberto Barton, a Peruvian physician, described the etiologic agent *(B. bacilliformis)*, but several years passed before this organism was accepted as the cause of Oroya fever and named in his honor.

Epidemiology

Historically, the distribution of bartonellosis has been restricted to the mountain valleys of the Andes Mountains in Peru, Ecuador, and Colombia between the altitudes of 500 and 3200 meters above sea level and primarily in valleys that are at right angles to the prevailing wind. The distribution of disease reflects the presence of the sand fly vector *Lutzomyia verrucarum*, which is seen only at these altitudes. The disease is usually acquired at twilight or soon thereafter because of the feeding habits of the insects. Within the region, the disease is endemic, but with sporadic epidemic outbreaks.[33,42]

Pathobiology

After inoculation by the sand fly, *Bartonella* organisms enter the endothelial cells of the blood vessels, where they proliferate. Microscopically, masses of organisms are noted within the cytoplasm of the cells lining the blood vessels and lymph channels, causing the lumen of the vessel to bulge. The organisms may also be found in reticuloendothelial cells in the lymph nodes, liver, and spleen, as well as within the bone marrow, kidneys, adrenals, pancreas, and rarely, the skin, heart, and lungs of infected patients.[9] They also parasitize erythrocytes, causing indentations and deformation of the erythrocyte membrane, membrane fusion, and entrance of the organisms into intracellular vacuoles, where they replicate.[10] Severe anemia results from destruction of the parasitized cells, with as many as 90 percent of the erythrocytes involved. However, all parasitized cells are not destroyed and no hemolysins or agglutinins have been recovered.[61] Cuadra and Takano[21] have shown that the parasites are located predominantly within cells, rather than on the surface. In the recovery phase, the rod-shaped organisms change to a more coccoid form and rapidly disappear from the blood.

A patient who survives the acute phase of Oroya fever may or may not experience cutaneous manifestations of the disease, which appear as nodular, hemangiomatous lesions ranging from a few millimeters to several centimeters. Light microscopy reveals angioblastic and histiocytic hyperplasia of the dermis. Numerous newly formed small vessels with endothelial cell proliferation are found. Mast cells, lymphocytes, and macrophages are present.[4] Electron microscopy demonstrates that the bacterial organisms are located within the verruga, extracellular in the fine fibrous interstitium.[57] In vitro studies have shown that *B. bacilliformis* stimulates endothelial cells, and in vivo studies have shown angiogenic activity. This finding may explain the similar pathologic findings of verruca and bacillary angiomatosis produced by other *Bartonella* spp.[4]

Clinical Manifestations
